My next note of the case is November 20th. Had increased to one hundred and twenty drops of K. I. Lid completely healed and seemed normal in appearance, mouth and throat healthy. As teeth were getting tender, ceased treatment for a period of three weeks.

Do not think she was seen again until March 5, 1892, when she consulted me on account of the irritation caused by one or two short eyelashes which had become turned in where there had been a slight loss of tissue. They were pulled out. She was again taking K. I. and mercury and was told to continue for a year, stopping at intervals when unpleasant symptoms arose.

When this case was first seen the negative history, small size of the sore, and apparent absence of an indurated base rendered a diagnosis uncertain, but after the second visit there was the usual excavated ulcer with a comparatively hard base, mucous patches in the mouth, and adenitis of the pre-auricular and submaxillary glands, and doubt as to the character of the sore no longer existed.

The cure by the antisyphilitic treatment seems to have been complete.

THE FALSETTO VOICE.

By O. PRESCOTT BENNETT, M.D.,

Chicago, Ill.,

Instructor in Laryngology and Rhinology, Chicago Policlinic.

Every voice, whether male or female, may be divided into registers, which, for convenience and simplicity have been designated: 1, The lower chest register, so named because the singer feels as though the voice came from the lower chest; 2, the upper chest register, coming from a little higher, and 3, the throat register, or the falsetto voice, which apparently comes from the throat. These three divisions or registers constitute the extent of the male voice. In the female voice, however, we have a fourth division, known as the second falsetto and, occasionally, a fifth, known as the head register. Each of these divisions can be differentiated from each other by the quality and volume of the individual tones within it.

As you all know, the voice of man should undergo a marked change at puberty. The puerile voice of the second register should become the masculine voice of the first, or lower register. Although the intensity may remain the same, the pitch should be much lower. This change is usually gradual, but in some it may take place quite suddenly.

In a few the voice remains unaltered or becomes higher, reaching the third, or falsetto register, although the boy may have become a man in every other respect. This condition frequently cures itself, some months or years after puberty. The patient in some as yet untried muscular effort finds that the voice of a man comes from the lower part of his chest, and thereafter the muscles controlling that register, which have heretofore been misused, respond to future demands and thus the cure is complete. Occasionally, however, this peculiarity may persist until somewhat later in life, when the patient's condition is made a very humiliating one, not only on account of the attention which he attracts at business and when at social gatherings, but also for the reason that the general public believe that there must be some lack of development in the genital apparatus of a full-grown man with a falsetto voice. It is needless for me to say that the public are entirely wrong in regard to their suppositions.

The difficulty is undoubtedly due to an improper use of the muscles of phonation. The patients speak with the abdomen retracted, which not only restrains but makes tense nearly all the muscles of the chest and neck. It is believed by Mulhall and Glasgow [1] to be due to a spasmodic affection of the arytenoid muscles, but to me it seems more like a voluntary effort which began at puberty and was continued from habit.

It is claimed by some, but denied by others, that it may be due to various diseases of the upper air-passages, or to a continual use of the voice in this register. I cannot comprehend how any pathological condition in these parts may cause this peculiarity, or how its removal will effect a cure. However, Cohen [1] has alluded to a case where it followed an acute laryngitis developed at the sea-shore, and Lincoln [1] to that of a bright young college student, who after taking the female part in a number of private theatricals was unable to get rid of it. An examination in the latter case revealed a large hypertrophy of the pharyngeal tonsil, and a removal of this enabled him to acquire a lower register.

This patient, before you, Mr. W. C. L——, a piano teacher, twenty-one years of age, and of American parentage, was referred to me for instruction by my former teacher, Dr. E. Fletcher Ingals. When he first consulted me, about a month ago, his speech was in quite a high falsetto key. He had never yet carried on conversation in any other register. He had at times been able to pronounce monosyllables in a lower voice, but had been warned by practitioners to discontinue it, for fear of doing injury to the vocal apparatus. He had come to look upon the falsetto voice as his normal one. The pronunciation of a few syllables in the lower register seemed to tire out his voice completely. It became higher instead of lower at puberty.

On examining the larynx, a month ago, there was evidence of marked congestion, the cords being quite pink, due undoubtedly to the over-strain of the voice. The nasal cavities, pharynx, and naso-pharynx were normal. There is very little congestion of the larynx at present, and I have no doubt it will entirely disappear in a short time. As he sings in the high register, you can see that the cords, both true and false, close more closely than they should. The glottis is reduced to a mere slit. The cords appear very narrow and tense, and the thin sharp edge alone seems to vibrate. Now as he sings in the lower register the vocal chink is much larger and has the shape of an ellipse. The whole width and length of the cords, and, in fact, the walls of the larynx also, appear to participate in the vibratory movements, but they vibrate more slowly than before.

The cure of this condition consists in convincing the patient that the high voice is not the normal one, and proving to him, in any way you wish, that he can converse and sing in the lower register.

When this patient first consulted me, after a prolonged laryngoscopic examination I told him, with an air of authority, that there was no trouble with the larynx whatever, and that the fault was purely a physiological one. I then depressed the chin of the patient, directed him to throw the shoulders back and to distend the abdomen. This was done, so that a large column of air might strike the cords in an unrestrained position. I then uttered several low gutturals and asked him to imitate me, which he did at once. Here I called his attention to the fact that he could speak in the lower register, and, should he desire a cure, he must continue to do so. A conversation

[1] Transactions of the American Laryngological Association, 1888.

then followed, both continuing to talk in the lower register, in which the patient's confidence in himself and in me was established, and the cure was almost accomplished.

It was very difficult for him to understand why speech in the higher register was more normal to him, as he could converse in that register with comparative ease, while the pronunciation of simply a few words in the lower register tired him very much. I told him this was due to the fact that he had used the higher one for seven or eight years, and that if he would follow out my advice, within a short time he would not only be able to converse in the lower one with comparative ease, but would then find it much more difficult to speak in a higher register. These statements were made in a manner meant to carry conviction.

It is necessary for the patient to notice each muscular effort for the first three or four days, or conversation will be resumed in the former high key. For this reason it would be well for him to remain away from business and acquaintances, unless it should be one friend who could correct him should he at any time resume his falsetto voice.

I had the patient read aloud ten minutes, two or three times a day, always assuming the position which I directed him to take at the first sitting. This time can be gradually increased, until speech in this key will seem quite natural to him. It has been just a month since I saw the patient first, and he now speaks in the lower register with considerable ease. He also informs me that it is with some difficulty that he resumes his former voice.

He complained of a dry, raw feeling in his throat for the first few days, but this was very much relieved by the application of cold packs to his neck.

In closing, then, remember, that the error is purely a physiological one, consisting in the faulty use of the voice. To cure it, it is simply necessary to convince the patient that the lower and not the higher register is the normal one, and demonstrate to him, in any way you wish, that, if he so desires, he can always use that register.

MALIGNANT CELLULITIS; OR, PHLEGMONOUS ERYSIPELAS.

By GEORGE T. WELCH, M.D.,

Passaic, N. J.

While ordinary erysipelas is an exudative inflammation of the skin, that which is known as phlegmonous erysipelas may begin in a wound, or from injury to the cellular tissue, by a blow or otherwise, without the skin being broken at all. In this case a true malignant cellulitis is rapidly developed, with intense burning pains, high temperature, delirium, a face dusky and anxious, tongue thick and coated, appetite gone, urine scanty. The skin does not always indicate the mischief existing beneath it; indeed, the enormous thickening of the limb or affected part is the earliest indication of the spread of the disease —the erythematous condition of the skin not appearing at the limit of the cellulitis until later on, when it may then spread beyond it. In a comparatively short time there may be entire necrosis of the whole adipose tissue of an arm or leg, if the progress of the disease is not actively interrupted by the knife and free drainage. The skin does not die so quickly as the tissue beneath it, but it is shortly blotched with gangrene, and entire sloughing of all the structure down to the frightfully vivid muscular system, and even beyond, is likely to result.

Hippocrates, in his account of the epidemics, begins one of his free-hand sketches with "The year was southerly, rainy; no winds throughout. Droughts had prevailed the previous seasons. The autumn gloomy and cloudy, with copious rains. Winter southerly, damp and soft. Early in spring, along with the prevailing cold, there were many cases of erysipelas" And crowded into a train of evils went fevers, diphtheria, ophthalmia, anthrax, and dysenteries, but the erysipelas grew constantly worse and worse. "In many cases," says he, "the erysipelas, from accident, sometimes from a very small wound, broke out all over the body Great inflammation took place. Abscesses ended in suppurations, and there was great sloughing of the flesh, tendons, and bones; and the defluxion, which seated in the part was not like pus, but a sort of putrefaction, and the running was large and of serious characters. In many cases both forearm and arm dropped off, and in some cases the whole femur and bones of the leg and foot were laid bare."

Epidemical erysipelas has occurred several times, in different parts of the world, during the present century, but perhaps nowhere else but in Hippocrates can be read so malignant a march of the phlegmonous variety. Sutton, describing the Indiana epidemic of 1843, says that "in one-twelfth of the cases diffuse inflammation affected the connective tissue in the axilla, or below the pectoral muscles, sometimes extending under the great muscles of the back and over the entire trunk, or the limbs, dissecting out the muscles, and often terminating in gangrene, with a discharge of long shreds of dead connective tissue resembling wet tow."

To one who sees for the first time a well developed case of phlegmonous erysipelas, the effect is startling, not to say horrifying. I have given an account in the "Transactions of the New Jersey State Medical Society for 1885," of a remarkable case that I attended in April, 1883. The patient, a sailor, had been ill for several days, and the local practitioner had, under a mistaken diagnosis, directed his treatment to the relief of inflammatory rheumatism. He was a man of spare habit, his left arm measuring eleven inches, while the affected right arm had a circumference of sixteen inches, and was boggy to the touch from shoulder to wrist, while gangrenous blotches appeared here and there, and a thin ichor exuding from the furthest inflamed and bloated lip of the disease, from which arose a noisome smell, gave the hideous impression that the limb had been swallowed to the shoulder by some venomous reptile. The countenance of the man was wild and haggard, and his temperature was 104° F. Free incisions were made and probably a pint of sanious pus rapidly escaped, affording some temporary relief, but in the end all the skin and connective tissues sloughed quite away, leaving the arm, from within one inch of the shoulder-joint to within three inches of the wrist, a bare, revolting, suppurating mass of flesh, on the surface of which veins and small arteries arose in bold relief. When a proper granulating surface appeared, on April 26th, I began the process of skin grafting, assisted at times by Dr. D. E. Roberts, and after about three hundred skin-grafts had been applied at various intervals, I had the satisfaction, in November, of discharging him with a soundly cured and useful arm. The satisfaction was altogether that of a duty well done, for I have never received the *quid pro quo* which gracefully closes an important transaction.

A man always pays dearly for his knowledge, however, and I have no reason to regret the price of mine. In reviewing the history of this case I formulated the resolve never to hesitate to treat even with heroic incisions in its early stages any similar disease that might come under my care. Incisions, drainage, and the thorough washing out of the sinuses with antiseptic fluids may not be the only treatment necessary, but they are by far the most important factors. The grave constitutional symptoms may be kept in abeyance by these means alone, and with generous diet, while the treatment by tonics, stimulants, and alteratives are only adjuvants. Two recently occurring cases in my practice confirm me in this opinion.

On April 24th last I examined a carbuncular swelling on the chin of Mrs. L. E. C——, which had begun as a small red spot and had rapidly become hard, raised with a minute vesicle, painful, and had a strangely angry appearance. Suspecting malignant pustule, I urged the part should be incised and cauterized at once, but the patient shrank from this method and parleyed for time. I had

therefore to content myself with poultices well mixed with listerine, which was at hand, and with opiates for the severe pain. On calling the next morning I found the patient anxious to undergo the operation, her pain having resisted anodynes and the chin in the few hours past having increased to an enormous size. Pointed lines of inflammation had curved-like flames about the lips, and up into the cheeks, and as days went by, features that had once been delicate and agreeable, became exaggerated and monstrous beyond description. The lips swollen to bursting, except for their tense leathery texture, became thrust outward and extended directly forward for nearly three inches, while the little glands hidden ordinarily and unnoticed in the mucous membrane, were now so many pouting mouths emitting pus and shreds of tissue; the nose became purple and broad; the eyes far apart and closed by puffy lids, from which hung rheum; abscesses developed in the loose connective tissue under the evelids, the tongue was swollen and foully coated, and the glands under the jaws brawny, while with deglutition nearly impossible, and pain vibrating like red-hot wires, the woman was generally able to control her intellect and to signify her consent to any and all the operations necessary to effect her cure.

The knife was used thirty-two times altogether, some of the incisions, as in the upper part of the face and about the nose, being carried to the bone; the upper lip was cut through in two places under the nostrils, and these incisions, together with the openings from the glands, most of which were large enough to admit a No. 5 probe, gave sixty-three avenues of exit for the purulent discharges. These had to be cleansed twice daily, and syringed out with antiseptic fluids. Often the mouth had to be sprayed with from one to two pints of a warm solution of corrosive sublimate before it could be freed of the ropy slime which encumbered it, and the patient be able to swallow medicines or food. Liquid food or liquid medicines could not be swallowed, but by thrusting semi-solid food, or boluses, partly into the throat the muscles of deglutition would rustily respond. Peptonized foods were used by the rectum at times, but the patient preferred per orem for all the pain it caused.

The temperature ran as high as $104\frac{2}{10}°$ F., and as low during recovery as 97° F. The heart's action was frequently hurried and the breathing quick and shallow, while copious perspirations weakened the system at times. Hypodermics of morphia and atropia were often necessary, and sometimes in large amounts, to control the pain. Arterial stimulants, antiseptics, tonics, concentrated foods, were freely administered. But the numerous incisions, made necessary to preserve the future integrity of the features, gave such advent to the septic material that there was no extensive sloughing, except from the upper lip and the chin, and a renewal of structure here, together with massage faithfully employed, has removed nearly all deformity, so that the patient has already recovered her former appearance in great degree, the scars have mostly disappeared, and in a year it will be difficult to demonstrate that this lady has passed through such an appalling crisis. I was happy in having the faithful attendance and assistance, through many trying days, of Dr. Myers, of Orange County, N. Y., the brother of the patient.

A still more recent case, and one of phlegmonous erysipelas, occurred in the left hand and arm of A. Z——, after the thumb had been bruised during the hilarities of a clambake, on September 11th. The skin was not broken, but by the 13th the thumb had increased to double its usual size, with well marked cellular inflammation. I anæsthetized the patient and laid the thumb well open, down to both phalangeal bones. Some fetid discharge occurred, and the wounds were dressed antiseptically. On the following day the inflammation had proceeded up the wrist and an opening was made there. Deep cellular inflammation proceeded, however, the forearm increasing daily in size, with intense pain and delirium. As soon as a boggy condition occurred, with the assistance of Dr. R. A. Terhune, I made sixteen deep incisions, a large amount of sanious pus and dark blood escaping. In three days I found it necessary to open each finger and various parts of the hand, and to increase the size of the opening at the wrist. By stroking the arm firmly and with deep pressure, toward the wrist, about one pint of pus escaped, and a stream of antiseptic water could be forced through the sinuses from an opening at the flexure of the elbow until it ran out at the base of the thumb. The fluid was then injected through the opening in the little finger, and escaped at various points. This method was carried out twice daily, at times, until all the sinuses healed and the skin regained its integrity. There was not a large amount of tissue-sloughing, and no deformity beyond stiffness of the fingers and hand is to be observed to day. The temperature was high in this case, with delirium at times, copious sweating for a week, increased heart-action, and a respiration of thirty-six per minute for four days.

I found strychnia, hypodermically used, in amounts of $\frac{1}{60}$ gr. would far better control the excessive heart action and hurried respiration than any other measure. It is not my intention, however, to speak of the medicinal treatment of these cases, for the proper remedies will suggest themselves to every competent physician when the critical time arrives, but to enforce the lesson that in malignant cellulitis a number of small incisions must be made at an early stage of the disease to relieve tension, and the patient should be anæsthetized so that the procedure may be conducted with care and precision, but when the presence of pus is suspected, or tissue disintegration, free openings should be made down to the muscles, or even to the bones, as the case may demand, and copious streams of warm antiseptic fluid should be frequently used, with antiseptic dressings between times.

DYSENTERY AND PTYALISM.

Dr. E. Dreifus, of New Orleans, writes: "Human nature is very perverse, but to show that this very perverseness may be utilized for a man's cure after all other means have failed the writer cites the following case:

"A patient named G——, by occupation a drayman, had been suffering for over a year with dysentery, in spite of all known remedies, which would control the disease for a time only, as he would disobey my instructions and pay no regard to the rules of diet set down for him.

"I had become almost disheartened when the thought struck me that if I could control his diet I could cure him; accordingly on my next visit I ordered him to take fifteen grains of calomel and told him to drink as much iced lemonade and eat as many pickles as he pleased. The next morning I was hurriedly summoned and found him suffering from a beautiful attack of ptyalism, in consequence of which he was unable to eat anything but fluid and bland food for three weeks. His dysentery got well."

URINE OF HIGH SPECIFIC GRAVITY.

Dr. E. E. Mather, of Williamstown, Mass., writes that he was recently consulted by a lady who wished to be bled. She complained of dizziness and an indescribable feeling in the head. She was forty-six years of age, married and the mother of a family, and regular in her monthly periods. Examination of the urine gave the following result: Quantity passed in twenty-four hours, 20 ounces; reaction, acid; no albumin; urea, 290 grains; sugar, the merest trace; specific gravity, 1.111. Dr. Mather had no urinometer that would measure this specific gravity, but it was kindly determined for him by Professor Mears, of the chair of chemistry in Williams College, by means of the Westphal balance. The patient gradually recovered her wonted health and spirits.

Progress of Medical Science.

Tuberculosis of the Eye.—In the *Gaceta Medica Catalana*, February, 1892, Julio Altabas reports a case occurring in a lad, aged seventeen, who, after eruptions, alopecia, and other manifestations of syphilis, complained of uncertain vision. There existed no photophobia, blepharospasm, hyperæmia, or lachrymation. There was some slight diffuse opacity of the cornea and a few small nodules on the left iris. In a side light the opacity was found to be formed by white dots on the posterior surface of the cornea, these being adherent exudations upon Descemet's membrane, the outgrowths of serous inflammation in the ciliary region. The pupil had normal reaction to light and responded to atropine. In the left iris there were small yellowish-white nodules, but slightly transparent. On the outer edge there were eight miliary granulations and others on the internal side. Toward the lower border of the iris there were also granulations. All were without vessels and pigment. With the ophthalmoscope, behind the crystalline lens and the anterior layers of the vitreous body various filamentary exudations were discovered, arising in the ciliary region and causing confusion of images upon the retina. Vision and the visual field were restricted. There was no pain, the general condition good, and examination of visceral organs negative. A diagnosis was made of tubercular irido-cyclitis in the left eye and tubercular cyclitis in the right.

Tuberculosis of the Iris.—In *Médecine Moderne*, May 19, 1892, Müller states that tubercular conditions of the iris are rare. In the case reported by him, characteristic yellowish tubercles were found on the inferior border of the iris. The patient presented hereditary manifestations of tendency to tuberculosis. The author thinks the eye had been infected by the hand, the tubercular bacilli travelling along the lymphatics and remaining in the lower border of the iris because of their own weight, which prevented them from rising higher.

Pityriasis Versicolor.—In the *Arch. de Méd.*, October, 1891, Molènes and Costilhes give a view of the pathogenesis and treatment of pityriasis versicolor. The disease is certainly contagious, though not to the same extent as favus. Certain writers consider that pityriasis is a sort of secondary symptom, occurring in persons having digestive troubles. In the greater number of the cases observed by the authors of the paper there were present digestive troubles and seborrhœa as well. The first indication is to destroy the microsporon by means either of tincture of iodine, resorcin lotions, or oleate of copper. The second is to tone up the digestive tract with drugs, of which purgatives and naphthol constitute the proper basis.

Digitalis in Kidney Disease.—Huchard has recently advanced the idea that digitalis, even in large doses, is not hurtful in affections of the kidney. On the contrary, it is useful, even in parenchymatous nephritis, for it diminishes the amount of albumin. Large doses at intervals of two or three weeks give good results.

Surgical Operations and Old Age.—In the *Arch. gén. de Méd.*, July, 1892, Blum affirms that old age is not necessarily a barrier to surgical operations, thanks to modern methods and intelligence. But certain precautions must be taken, such as preparing the patient for the ordeal, choosing the right moment when every function is normal, etc. As far as possible, general anæsthesia is to be avoided. Cocaine or chloroform to the point of drowsiness often serves admirably for the aged, who are not particularly sensitive to pain. Warm cloths should envelop every part of the body that is exposed, except the direct area of the operation. The room should be very warm. Esmarck's bandage should not be used; never in atheromatous conditions. Scrupulous antisepsis, to hasten union by first intention, should be the rule, in order to get the patient out of bed as soon as possible. The aged should be carefully and frequently fed.

Vitality of the Typhoid Bacillus.—Experiments reported by Karlinski, *Zdrowie*, Varsovie, 1891, demonstrate that—1. The typhoid bacillus lives only three months when buried in the earth. 2. That the typical bacillus mixed with excrement does not live as long as the bacillus in pure cultures, owing to the action of microbes native to excreta. 3. Water added to earth diminishes the vitality of microbes. 4. Just beneath the surface, the typical bacillus resists more energetically the action of other microbes than at a greater depth. 5. On the surface of the ground, owing to the influence of sunshine and rain, the bacillus' vitality is lessened. 6. During the putrefaction of organs from typhoid fever cadavers, there is great elevation of temperature, the typhoid bacillus being found for more than three months.

Hepatic Sclerosis and the Hepatic Cell.—Grandmaison, in his *Thèse de Paris*, 1892, states that, as regards distribution, hepatic connective tissue hyperplasia is quite exceptionally systemic, and therefore the inflammatory development of connective tissue is not exclusively the result of vascular irritation. In acute and chronic hepatic lesions sclerosis develops more extensively around the cells than around blood-vessels. Cellular changes are profound in proportion to proliferation of connective tissue, and are the chief factor in the pathogenesis of hepatic sclerosis. Atrophy of the hepatic cell leaves a void that is quickly filled up by cicatricial connective tissue.

Nasal Asthma Alternating with Circumscribed Œdema of the Skin.—Rethi, of Vienna, in *Archives internac. de Rhinolgia*, April, 1892, reviews the different theories of asthma, and admits that in the majority of cases of nasal asthma it is a question of nasal nervous reflex. The case cited occurred in a girl, twenty-two years old, subject to attacks of asthma, in which the nose became stopped up, the nostrils regaining their usual freedom as the attack wore off. With some hesitation, cauterization of the mucous membrane was suggested. For a certain time every night after this procedure there would be a rather extensive œdema of the skin, or an asthmatic attack alternating regularly until the nasal stenosis was completely overcome, when both morbid manifestations disappeared permanently.

Tachycardia.—Lacerna (*Thèse de Paris*, 1892) considers essential and symptomatic tachycardia that may be of organic or nervous origin. In the latter case the condition is either direct or reflex. Direct tachycardia is due to paralysis of the inhibitory system (nervous centres, pneumogastric), that gives symptoms similar to section of the pneumogastric nerve and is of grave prognosis. Reflex tachycardia, due to irritability of the sympathetic, presents a hopeful outlook. It has but little effect upon the heart proper beyond some slight dilatation, and induces no permanently marked disturbance of the general circulation. It is seldom accompanied by pulmonary, laryngeal, and gastric phenomena. Accompanying symptoms are distinctly vaso-motor, as coldness of extremities, pallor or flushing of the skin, and dilatation of the pupil.

Early Symptoms of Neurotic Asthma.—Before the Congress of Balneology, at Berlin, in March, 1892, Goldschmidt made a contribution to the study of neurotic asthma that usually appears about the time of puberty or even later. Though rare in babies and young children, it does occur at a very early age in subjects showing many other morbid symptoms. Little children who are asthmatic are nervous, timid, irritable, very sensitive to cold. There is hyperæsthesia of the skin and consequent eczema. One symptom shows itself early in future asthmatics, and that is impossibility of deep breathing without coughing. The essential treatment is judicious hydrotherapy, combined with indicated internal remedies. Compressed air combats anæmia, relieves the swelling of the bronchial mucous membrane, but frequency and duration of attacks are influenced by it.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, November 5, 1892.

THE SERUM TREATMENT FOR PNEUMONIA.

AMONG the first practical applications of the experimental investigations regarding immunity were those of the Klemperer brothers. They had first found in the cultures of pneumococci a toxine which produced pneumonia in rabbits; later they discovered that rabbits which had been inoculated with the serum of animals and men convalescent from pneumonia, were invulnerable to injections of the pneumotoxine. Applying these results to men, they injected subcutaneously the serum of persons who had just recovered from pneumonia in six cases of ordinary pneumonia. In all these cases the crisis appeared within twelve hours, though there was some return of fever later. The patients all recovered. Neisser reports three cases, in all of which recovery took place, though the specific effect of the serum injections was not so clearly demonstrated. Redner has reported twenty cases treated by the injections. In all there was a favorable result, but in a good many this could not be attributed to the treatment alone. Other cases have been treated by C. Janson.

The first to apply this method of treatment in America, so far as we know, were Drs. W. E. Hughes and W. S. Carter, of Philadelphia, who report one case in the *Therapeutic Gazette*, and give a summary of previous experiments, upon which we have drawn. Drs. Hughes and Carter report the history of their case with commendable care in detail. The patient was a male, thirty-five years old, a hard drinker, who after a two weeks' spree developed a chill with cough and intercostal pain. Three days later he was found to have a temperature of 104° F., with consolidation of the right lower lobe and the beginning of a similar involvement of the left lower lobe. On the fourth day of the disease he received an intravenous injection of three hundred cubic centimetres of defibrinated blood taken from a negro convalescent of pneumonia. The injection was followed by a chill and purging; the temperature, which was 101.8° F. before the transfusion, was 101.6° F. after it. Next day it rose to 104.4° F., and subsequently oscillated between 103° or 104° F. and was normal for three days, when the lungs seemed pretty clear, the temperature was normal, and convalescence began. The authors attribute some specific effect to the injection, because the lungs began to clear up at once despite the fever. We think it very doubtful if the case would be received as one contributing much to one's confidence in serum therapeutics. However, the patient recovered despite his alcoholic pneumonia, and that is a good deal. Drs. Hughes and Carter advise against the use of defibrinated blood, and think that serum collected from a blister, or by letting drawn blood stand, is safer and more efficient. At least fifty cubic centimetres of serum should be used, and it should be injected beneath the skin rather than thrown into the veins.

THE JUDGE AND THE DOCTOR.

A MOST extraordinary decision has recently been given by Judge Levy, of California, in the case of Dr. C. Ellinwood, who had a claim of $30,000 for medical services rendered to the family of a deceased millionaire. The executors of the estate and the three heirs all allowed the bill, but the Judge thought it too much, and cut it down to $10,000! The Judge says in his opinion: "Although inexperienced in the charges of medical gentlemen for professional services, I am at a loss to recall a case where such an amount has been charged. I am of the opinion that the services rendered for one year's time were not of the value of $30,000, but a fair, reasonable, and just compensation would be $10,000, for which amount this claim is allowed."

Yet lawyers often charge a much larger fee for services of much less intrinsic value. We hope that Judge Levy may be taken pleasantly and chronically ill, and then that Dr. Ellinwood may be called to attend him.

THE EYES OF CALIFORNIA STUDENTS.

IN a paper published in the *Pacific Medical Journal* for October, 1892, Dr. W. F. Southhard reports the results of the examination of the eyes of three hundred and eleven students in the University of California. The work was intended to supplement the other physical examinations of the students, and observations made abundantly prove the value of such kind of work. The students examined were Freshmen, ranging in age from sixteen to twenty-seven, the great majority being between the years of seventeen and twenty-one. There were 62 females and 249 males. It was found that among the males 65.64 per cent., or two-thirds, had defective eyes, although 68.67 per cent. had vision of $\frac{20}{20}$. About one-third (36.94) of the total examined were hyperopic; 4.81 per cent. were myopic, and one-fourth (24.49 per cent.) were astigmatic. Among the 62 female students the proportion and distribution of defects were very nearly the same as in the males.

Comparing these results with those of an Eastern college (Amherst), the statistics of Derby show myopia 35.47 per cent., and hypermetropia about fifteen per cent. Statistics of Eastern pupils show, on the whole, an average of about twenty-five per cent. of myopes among persons of eighteen to twenty years of age. In German schools the myopia runs up to forty and fifty per cent. Tschering's statistics of Danish university students gave only 3.8 per cent. hypermetropia, and 32.3 per cent. of myopes. Statistics regarding hypermetropia have not much value for comparative use; but it is interesting to note the fact that on the Western edge of civilization myopia is at a minimum, while hyperopia is quite prevalent, the

conditions being very nearly the reverse of those in such a country as Denmark.

There have been a great many examinations of the eyes of school children and college students; but our social conditions and educational methods are constantly changing, and there is every reason why such studies should be carefully and continuously pursued. The eye is an organ that responds rather quickly to its change in environment, and is in many respects a delicate test of the soundness of methods of physical and mental training. It is extremely necessary, however, that oculists agree more completely as to what should be classed among refractive errors in making up statistics, and as to the technique to be pursued in making the examinations.

TOXIC NEUROPATHIES.

A German physician, Oppenheim, has recently called attention to the effect of the direct and indirect actions of poisons upon the nervous system. Their direct action is to produce typical disorders, as paralysis, due to lead, alcohol, arsenic, or the diphtheritic virus. An indirect effect of toxic substances is the circulatory disturbances they produce, as arteritis and arterio-sclerosis. These conditions obtain in syphilis, alcohol, and lead-poisoning. Functional diseases, as hysteria, neurasthenia, and epilepsy, may also owe their origin to various intoxications. But of the general cachexia that poisons induce, it is quite possible for nervous affections to arise. And their influence does not end here, for irritants like the foregoing exercise distinct action upon the course of intercurrent disease. Traumatic peripheral paralysis and radial paralysis have marked affinity for alcoholic subjects. Alcoholism and plumbism constitute in themselves a definite predisposition to the development of the professional palsies. They aggravate every known form of nervous disease. Hence it will be perceived that there is not only the neurotic taint as a factor in disorders of the nervous system, but a toxicopathic taint as well.

ETIOLOGY OF CHRONIC HEART DISEASE.

In *Médecine Moderne*, July 21, 1892, there is an abstract of Schott's paper on chronic heart troubles and their causes, based upon the study of seven hundred and fifty cases, divided for convenience into two classes, endo-cardiac affections and neuro-muscular disorders. Heredity is an important factor. Among the endo-cardiac affections acute rheumatism plays the most important part; but other infections, as scarlatina, typhoid fever, influenza, measles, puerperal fever, can also produce valvular troubles. Arterio-sclerosis, syphilis, diabetes, icterus, and exophthalmic goitre, are sometimes causes. In neuro-muscular disorders emotion and mental overwork, combined with sudden or prolonged physical fatigue, are the chief causes. Fevers act unfavorably upon the neuro-muscular mechanism of the heart. This is as much the fault of specific poisons in the blood as of high temperature. Chlorosis and anæmia often produce heart disturbances; here care should be taken not to confound effect and cause. Alcohol, tobacco, coffee, tea, and too substantial diet have a like effect. Exaggerated thinness at puberty is also unfavorable to the heart. Constitutional conditions favoring endo-muscular disorders are lithæmia, syphilis, and arterio-sclerosis. Everything that impedes circulation of the blood, as emphysema, pleuritic and pericardiac exudates, mediastinal tumors, predisposes to chronic cardiopathies. Nervous disease, functional or organic, is a powerful factor in the development of cardiac difficulties. And Oertel's cure is also a cause. There may be many others, but Schott confines himself solely to those personally known to him.

PSORIASIS.

In the *Annales de Médecine*, 1891, Dr. Georges Thibierge publishes some interesting observations upon the subject of psoriasis, one of the most common diseases of the skin, though less frequent in Austria and America than in France and England. It is a chronic inflammatory infection, characterized by dry, red, primarily roundish patches, covered with imbricated, silvery, adherent scales, occurring chiefly on the extensor surfaces. Bazin recognized several different kinds of psoriasis, among them the arthritic, herpetic, and syphilitic; but English authors incline to the opinion that there is but one psoriasis. The scales resemble thin drops from a wax or tallow candle, easily pulverized, and may be bent like gold-beater's skin. Pricking off the scales exposes to view a number of bright red dots which bleed easily, and are the apices of the hyperæmic papillæ. The disease may be general, but it is more often upon the trunk, on the back, and especially on the chest. It attacks two regions by preference, the level of the throat and the knee, yet it may appear almost anywhere. The two abnormities most resembling psoriasis are seborrhœal eczema and late manifestations of syphilis. Anatomical changes consist in thickening of the horny layer of the skin, increased development of the rete layers, except over the papillæ, and deep down, a disappearance of eléidine. In the upper part of the corium there is cell exudation and dilated vessels.

Psoriasis is not congenital, though it appears in babies, in patches about the elbows and knees preferably. Applications of tincture of iodine or black soap will often serve to cure this infantile psoriasis. Before twenty the disease is rare, and most common between twenty and thirty. Treatment cleans up the patient, so to speak, but permanent cure is not obtainable by any remedy yet known. Alcoholism, pregnancy, or lactation may induce a relapse; and unrecognizable causes also bring about this unhappy result. The disease is not fatal to life, but often fatal to activity and happiness, its peculiar characteristics rendering its victim repulsive in shops and offices, and in general society. Heredity, a lowered standard of health, mental emotion, overwork, and injury, are set down as causes. Recent cases are worse in winter, older cases in the spring. It attacks both sexes indiscriminately, and rank and occupation have no influence.

Unless there are indications for arsenic in the general condition, the writer considers its employment questionable. Haslund, of Copenhagen, has obtained excellent results with iodide of potassium. Certain dermatologists think external remedies the only ones necessary. Oil of cade or tar ointment constitutes the classic treatment. But oil of cade has a disagreeable odor, acts more energetically than

chrysophanic or pyrogallic acid, and often produces acne. Chrysophanic acid is quick in action, inducing desquamation rapidly; but it requires most careful watching, as it stains linen and the hair, turns the skin purple, and brings about serious inflammations if it comes in contact with mucous membranes, to say nothing of a general intoxication. It may in some instances provoke violent skin lesions, or glandular and phlegmonous inflammation. Chrysophanic acid may be used with gutta-percha and chloroform, ten parts of the acid, ten of gutta-percha, and one hundred of chloroform. The latter, evaporating, leaves a protective substance that keeps out air and foreign bodies. Pyrogallic acid may also bring about constitutional disturbances, though less poisonous than chrysophanic acid. It stains linen black. Naphthol is without danger of any kind, but its action is slow. Aristol is uncertain. To remember that treatment can be palliative only is to be free from surprise and disappointment.

PNEUMONIC PARALYSIS.

This is the subject of Boulloche's *Thèse de Paris*, 1892. Pneumonia, like other infectious diseases, may induce toxic paralysis during the acute stage, or during the period of convalescence. That occurring during the acute stage may exist in some circumscribed location, resembles the hemiplegic type, and is often associated with aphasia. In the aged, this paralysis may be the only symptom of pneumonia. Paralysis occurring during the period of convalescence is usually diffuse, most marked in the lower extremities, and capable of bringing about muscular atrophy. In paralysis due to pneumonia there is often no definite lesion whatever. Then again, there may be found more or less trivial manifestations of abnormal conditions of the brain, as meningitis and softening; and similar slight appearances of meningo-myelitis, softening, and multiple sclerosis in the cord.

Uterine Fibroid and Syphilis.—Prochownick has distinctly traced a relation between constitutional syphilis and fibromyoma of the uterus in certain cases which he has reported. The administration of mercury and iodides led, in these cases, to a distinct, though not very marked, diminution in the size of the tumor, while pain and flooding disappeared. To the objection that these so-called fibroids might have been gummatous deposits in the uterus he replies that the hardness and other characters of the tumors all indicated fibroid disease, while there were no signs of breaking down and no cicatricial contractions on the surface of the tumors, such as are observed in gummata. In two cases of fibroid disease, where the patients were free from syphilis, iodides and mercury did no good whatever. Prochownick has no belief in any specific action of these drugs on fibroids. On the other hand, he finds that syphilis may set up chronic metritis and endometritis. Such cases defy the curette and other kinds of local treatment, but may speedily be cured by antisyphilitic remedies. Prochownick is not inclined to attempt any explanation of the origin of myoma uteri. He inclines to the theory that the germs of myoma lie dormant for years, and set up a tumor in response to some undetermined stimulus which most probably arises in the blood vessels.—*British Medical Journal.*

News of the Week.

The Corner Stone for the new building of the Post-graduate Medical School and Hospital will be laid some time during November. The address on the occasion will be delivered by Dr. T. Gaillard Thomas.

Increase of Insanity.—According to the *British Medical Journal* the percentage of the insane to the general population has steadily risen during the past ten years from 28.83 to 29.88 per ten thousand.

Queen Victoria's Ostrich has been homesick, necessitating the administration of castor oil. Shortly after the dose the royal bird became quite animated.

Dr. Edmund C. Wendt, the Medical Commissioner of the Medical Record to the Riviera, is on his way to his home in this city. His interesting reports while abroad will be remembered by our readers.

The Southern Surgical and Gynecological Association.—The next meeting of this Association will be held in Louisville, Ky., November 15, 16, and 17, 1892. The preliminary programme, recently published, gives promise that this will be an interesting meeting. The President of this Association is Dr. J. McFadden Gaston, of Atlanta, Ga. Members of the medical profession are cordially invited to attend.

Dr. J. Collins Warren, of Harvard Medical School, has accepted the Executive Presidency of the section on Medical Pedagogics of the Pan-American Medical Congress.

Dr. Frederick Peterson has been appointed Professor of Neurology in the University of Vermont.

Medical Society of the County of New York.—The eighty-seventh annual meeting, October 24th, was devoted to the election of officers and reading of reports. The election resulted as follows: *President*, C. C. Lee; *First Vice-President*, William Stevens; *Second Vice President*, Robert Abbe; *Secretary*, Charles H. Avery; *Assistant Secretary*, William E. Bullard; *Treasurer*, John S. Warren; *Censors*, G. H. Fox, A. S. Hunter, L. C. Gray, C. H. Knight, R. Van Santvoord. The annual dues were continued at three dollars. The Treasurer's report showed a balance in the treasury. The propriety of taking steps to acquire a permanent home for the Society was discussed. Among the good results of publishing a directory was that it had led to prompt payment of dues, there being at present about one-tenth as many delinquents as formerly. No prize was awarded for essays.

Nineteen Papers on Club-foot were read at the last meeting of the American Orthopedic Association, and the subject ought now to rest on a firm basis. Such firm basis seems to be that there is no single treatment for club-foot, but that some cases should be treated by operation, and others should not; and that the operations indicated are sometimes bone-cutting, sometimes tendon-cutting, sometimes *brisement forcé*, and sometimes combinations of all these.

Medical Women in England.—The recent decision of the British Medical Association, to admit women as members thereof, has brought out the fact that the number of women whose names appear on the Medical Register is much greater than was supposed. A few years ago there

were but eight women practising in England; now, however, there are one hundred and thirty, and besides these, one hundred and forty more women are studying medicine at various schools in Great Britain and Ireland. At this rate of progress women practitioners may be expected in time to form a fair element—only in numbers, by the way—of the medical profession in this country. But their best sphere of labor is undoubtedly in India, where medical women are really much needed, and where they can be relied on to do necessary and useful work.—*Medical Press.*

Education and Marriage.—About forty-five per cent. of Vassar graduates are married.

Professor Billroth's Jubilee.—A series of festivals has recently been held at Vienna in commemoration of the commencement of the teaching career of Professor Billroth. The event has been converted into a sort of congress, which was inaugurated on October 8th by the assembling of the former pupils of this distinguished surgeon, in order to testify their gratitude for the advantages they had derived from his instructions. On this occasion Professor Czerny, of Heidelberg, was deputed to present to Professor Billroth a volume containing a record of his principal surgical works, and entitled "Contributions to Surgery." In the evening of the same day a dinner was given to Professor Billroth, at which numerous congratulatory speeches were made. The jubilee extended to the 11th, on which day his friends and admirers assembled to listen to an address by Professor Albert. The commemoration has excited great enthusiasm in the medical world of the Austrian capital.

Medical Practice in Mexico.—By Mexican law, says a correspondent of the *Lancet*, no person is allowed to practise medicine or surgery without having passed an examination conducted by properly appointed examiners. This examination consists of written papers and *viva voce* examination of cases in hospital thesis, and all must be passed in Spanish. This latter proviso may sometimes be relaxed. About a year ago I intended to try for a Mexican degree, and I wrote on the subject to the legal adviser of the firm I work for, asking how to proceed. He wrote me a long reply, in which he told me that it was quite useless my attempting to obtain a degree in Mexico City, as the examiners would pass no man not holding a qualification from Madrid (?), Berlin, or Vienna, but at the same time telling me I might obtain a degree in Zucatan or Menterez, if I got good letters to persons in authority. Practically, in country districts one is not interfered with, as the so-called doctors (Mexicans) are themselves unqualified men. In town men arrange with a Mexican doctor to sign death certificates. In my particular case, as I am a doctor only to men employed on these works, I am let alone; but I have to keep on friendly terms with the town authorities, and obey all sorts of peculiar rules and regulations.

The Pennsylvania Society for the Prevention of Tuberculosis has been formed and has commenced its crusade against this great modern scourge by educating the public by the publication of tracts for gratuitous distribution. The first one has just been issued; it is entitled "How to Avoid Contracting Tuberculosis." It contains much good advice, and is based upon the scientific demonstration of the contagious character of the disease, upon which the members of the Society evidently believe it is impossible to lay too much stress, and they have very little to say about "predisposition" or "the pre-tubercular stage," which we used to hear so much about.—*Journal of American Medical Association.*

First Successful Case of Symphyseotomy in this Country.—At the last meeting of the Philadelphia County Medical Society, Dr. Barton Cooke Hirst reported a case of symphyseotomy at the University Maternity Hospital, upon a young German woman with a kyphotic pelvis. The operation was readily done, and a live infant, a girl of normal development, was promptly delivered. The mother bore the operation well, and the infant's life was saved, which is a better result than could be obtained by craniotomy and not less good than Cæsarean section. It is believed that this case is the first in the United States in which symphyseotomy was performed as a substitute for the more grave Cæsarean operation, and its results warrant the hope that it may be found an efficient substitute for the latter in appropriate cases.

The Place of the Late Dr. Formad, of the University of Pennsylvania, has been taken by Dr. Joseph Macfarland and Dr. Henry W. Cattell.

Trinity Hospital.—Dr. Arthur L. Fisk has been appointed on the attending staff.

New York Hospital.—Dr. Arthur L. Fisk has been appointed Surgeon to the out-patient department, in place of Dr. Charles A. Powers, resigned.

Why Medical Science Makes Slow Progress.—In his "History of England in the Eighteenth Century," Mr. Lecky has the following passage: "Hardly any other of the great branches of human knowledge is at present so backward, tentative, and empirical as medicine, and there is not much doubt that the law of supply and demand is a main cause of the defect. Almost all the finer intellects which are devoted to this subject are turned away from independent investigations to the lucrative paths of professional practice; their time is engrossed with cases most of which could be treated quite as well by men of inferior capacity, and they do little or nothing to enlarge the bounds of our knowledge."

The Incomes of Berlin Physicians.—In Berlin there are 1,747 doctors, nearly half of whom make less than $750 a year. Only about 170 make more than $2,500. These figures are based on the income-tax, and it is just possible that the Berlin physicians take an especially gloomy view of their collections at the time of certifying to their financial condition.

Statues of Eminent Doctors.—"I cannot recall to mind," writes the Paris correspondent of *The Lancet*, "where in England there is to be found a statue to any of the good and great men in our profession who have an undoubted claim on humanity, unless it be the single exception of Harvey's in Folkestone. Not so throughout France. Paris alone has statues to Broca and others, and will shortly have one to Ricord, for which the President of the Republic has approved the sanction of the Prefect of the Seine authorizing the erection of the statue in one of the public places of Paris. To-morrow also will be inaugurated at Morlaas the bust of Depaul, formerly the

well-known professor of obstetrics at the University of Paris." America has as yet but one statue of a medical man, viz., that of Dr. Sims.

Inebriety among Women.—The *British Medical Journal* gives a startling picture of the increase of inebriety among women in England, and also in other parts of the world. The number of women convicted of drunkenness in England and Wales, rose from 5,673, in 1878, to 9,451, in 1884. Last year 33,000 females were convicted of drunkenness in the United Kingdom. In London in one year the increase of convicted women was 500. In Glasgow 10,500 women were sent to prison. Of this number 450 were sent to jail from six to thirty-four times during the year. In Ireland the champion female inebriate record-breaker has been arrested over 700 times, and she is only forty years of age. In this city about 10,000 women are arrested yearly for drunkenness.

St. Luke's Hospital.—The annual meeting of the Board of Trustees of St. Luke's Hospital was held on St. Luke's Day, October 18th. Dr. Frederick Barnard, who has been Assistant Superintendent for the past twenty-three years, tendered his resignation on account of ill-health. Dr. L. Bolton Bangs resigned his position as attending surgeon, and he and Dr. Frank H. Markoe were appointed consulting surgeons.

Dr. Robert W. Greene, of this city, died suddenly on October 28th. He was born in Providence thirty-two years ago and was graduated from Brown University and, in 1887, from Bellevue Medical College in this city. For a time he was an assistant to Dr. Janeway.

Local Medical Practice Law.—The city of Bridgeport has enacted an ordinance prohibiting irregular and unlicensed physicians to practise in its limits. Connecticut has no medical practice law, and Bridgeport is taking measures for its own protection. The ordinance will undoubtedly have a good effect in stimulating general legislation as well as in clearing its neighborhood of quacks.

Hartford County Medical Association.—The centennial of the organization of this society was celebrated on September 26th. Many speeches were delivered by members and by medical and non-medical guests, followed by a reception and dinner.

The New Clinical Amphitheatre at the Philadelphia Hospital was opened on Saturday, October 1st.

Medical Women in Bosnia.—Bosnia has enacted a law for the appointment of a medical woman to the capital of each district, with the official title of *Wundirztin, i.e.*, a grade lower than that of Doctor of Medicine.

How Does She Do It?—Chicago, located on low ground, with poor water, bad streets, incomplete sewerage, and an epidemic of typhoid fever, announces a death rate of 17 per 1,000. New York, with pure water, good sewers, and no epidemic has a death-rate of over 22 per 1,000. One explanation may be that Chicago has a population of 1,400,000, as working basis for vital statistics.

A Fit Appointment.—Dr. John C. Sundberg, a former editor of the *Pacific Medical Journal,* has been appointed United States Consul at Bagdad, a post of considerable importance commercially as well as scientifically, as the Doctor will make important investigations relative to epidemiology and contagious diseases under the direction of the Smithsonian Institute at Washington. It gives us great pleasure, says the *Journal,* in chronicling Dr. Sundberg's good fortune in obtaining this post, because we believe he is one of the ablest men in the profession to fill it. He is fond of India, having had several years' experience in that country, and he is particularly well qualified on account of his scholarly and linguistic attainments, speaking not only Norwegian—his native tongue—Swedish, Danish, German, and French, but also several oriental languages, including Persian, Arabic, Hindustani, and Bengali.

Culture and Professional Success.—The short paper on "Culture and Professional Success," which appears in the current number of the *New Review,* from the pen of the late Sir Morell Mackenzie, is strongly in favor of a wide general culture as the best preparation for the more special training which every profession demands from those who aspire to enter it. The author's grounds are various, but they may be summed up under two heads: First, that such culture confers breadth and flexibility of mind and renders the acquisition of special knowledge easy; and, secondly, that it develops a knowledge of human nature, and hence assists in enabling us to treat our clients or patients not as mere "cases," but as complex, sensitive, and highly organized men and women.

The Mecca of Medical Women seems to be Switzerland. That country was one of the first to open its university doors to the ladies, and it has been popular with them ever since. At the present session there are, among 349 foreign students, 148 *dames* and 201 *messieurs.* The Swiss ladies themselves do not take so kindly to medicine, apparently, for there are only 9 natives in the medical schools. Among the 953 medical students in Switzerland, one-sixth are women.

One Dollar Commission.—Not long ago, and possibly at present, one or two drug-stores of a large American city kept a series of Yale-locked boxes behind the prescription counter, each marked with the name of a physician of the city. The boxes had a slot sufficiently large to admit a silver dollar, which, wrapped in the prescription, was placed in the box, when, by the careful direction of the writer, the patient had been piloted to the store. The special key was carried by the honorable gentleman whose professional card was upon the box. If this seems ancient history, there lies before us a personal letter to a Philadelphia physician, dated September 30, 1892, in which, with blank order-checks, etc., at command, a "mineral spring" company offers to give the physician one dollar for "each order, at $5 cash with order, you send or cause to be sent to us," for a dozen bottles of the medicinally and miraculously potent water. "It must not be understood as a discount allowed to your patient."—*Medical News.*

The Hospital Saturday and Sunday Association met on the evening of October 17th, at St. Luke's Hospital, Mr. George Macculloch Miller presided. A committee consisting of the Revs. Thomas M. Peters, W. T. Chambers, and Henry F. Day was appointed to interest the churches in the hospital collection to be made at the different churches on the last Sunday in the year. Three hundred hospital collection boxes are to be placed in private residences.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 20, 1892.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

THE meeting was held under the auspices of the Surgical Section, DR. JOSEPH D. BRYANT, Chairman.

Artery Forceps.—DR. CARL BECK presented an artery forceps which claimed to permit of rapid ligation without injury to the vessel or tissues. It could also be used as a needle-holder.

Intubation versus Tracheotomy for Acute Laryngeal Stenosis in Children—To what Extent, if at all, has Intubation Supplanted Tracheotomy?—DR. JOSEPH O'DWYER read a paper, opening the discussion on this subject. He said that while it would have been very easy to prepare a long paper upon it, he had found it difficult to prepare a short one. By acute stenosis of the larynx was meant the stenosis which occurred in fibrinous, diphtheritic, or membranous croup. If unrelieved by mechanical means this would prove fatal. The disease still continued one of the most fatal of early life. An illustrative case was related in which, in spite of intubation, which gave complete relief for about twelve hours, the temperature, pulse, and respiration increased, the latter to about eighty, and thirty hours after intubation the child died. Some would say there must have been broncho-pneumonia, yet the autopsy showed none, death having resulted from blocking of the bronchial tubes with pseudo-membrane as far as could be traced.

Not uncommon causes of death were catarrhal pneumonia, nephritis, and paralysis. If mechanical obstruction from membrane in the larynx alone were the only question in these cases, intubation would certainly be a most efficient method and should have scarcely a failure.

As it would be impossible in a brief paper to answer all the charges that had been made against intubation, especially the accidents and dangers, he would confine his remarks upon this part of the subject to a consideration of criticisms in a paper by Dr. Lovett, of Boston, in which was recited the experience with intubation in the Boston City Hospital. The principal, if not the only, cause of the bad results obtained at that institution was that the operations were performed by a number of different men, more or less inexperienced, who appeared on the staff by rotation. The only difficulty met with by experienced operators was the tendency of the tube in a few cases to engage in the subglottic fold, and yet the experienced operator meeting with such difficulty knew how to overcome it. An analysis of the accidents cited by Dr. Lovett showed clearly that they were in almost all instances due to the operation having been done by inexperienced men or to carelessness. Sudden death occurring while the tube was in the larynx must be due either to obstructing membrane or to heart paralysis, but more frequently did pushing of membrane before the tube give relief than cause stenosis.

One of the gravest objections which had been offered to intubation was the difficulty afterward of feeding. When, however, the tube was introduced with care and skill this difficulty existed only exceptionally. If the parts were injured by clumsy efforts to pass the tube, it would be remarkable if the little ones did not suffer during deglutition afterward. When the operation was really called for the patient was getting but little air, and this little could be cut off only a very short time without endangering life. Even ten seconds was not safe. To pass the tube, then, as speedily as should be done and cause no injury required practice, which should be gained on the cadaver and in different subjects, for some subjects were more difficult to intubate than others. Tracheotomy implied no such danger. No great amount of surgical skill was required to do tracheotomy, but subsequent intelligent nursing was almost an absolute necessity. One practice, therefore, called for trained nurses, the other for a trained operator.

It appeared that at the Boston City Hospital intubation had been followed by about twenty per cent. recoveries, and tracheotomy by about twenty-nine per cent. One could hardly believe that the smaller number of recoveries following intubation could have been due to the operation so much as to the manner in which it was performed, for the percentage of recoveries at the Willard Parker Hospital had been thirty-eight, and another operator had had thirty-four per cent. of recoveries in over one hundred cases. In fact, the percentage of recoveries at the Boston City Hospital had been lower than any individual results that he knew of, and there were sufficient reasons for it.

Of the factors which influenced the prognosis in intubation and tracheotomy, age was the most important. The results of intubation in the first year of life were almost *nil;* the third year was better than the second, and after the third year and a half age did not play an important rôle. Lovett had said that tracheotomy saved one in fourteen under two years, while intubation in Dr. O'Dwyer's cases had saved one in six

Secondary tracheotomy was not likely to prove of much avail when intubation failed because of membrane extending to the trachea. The author thought that from all the facts presented the conclusion seemed inevitable that intubation accomplished practically all that tracheotomy accomplished without any of the unpleasant features of the latter operation.

DR. LEWIS S. PILCHER, of Brooklyn, continued the discussion with a paper. He thought that in any case of exudative laryngitis it was absolutely impossible to exclude the existence of diphtheritic infection. This was of importance in considering operative measures. The laryngeal affection was but the effect of a general disease. The general effects of that disease were to be guarded against, and local emergencies were to be prepared for.

Granting that both intubation and tracheotomy would remove the laryngeal stenosis, which was best adapted to assist the system in its struggle against the general infection? The answer to this question involved three points—blood aeration, local cleansing and antisepsis, and general nutrition.

Intubation as well as tracheotomy met the first point, and intubation admitted air which was warmed in the natural passages, but it did not admit so well of meeting further obstruction down the trachea, and it was also liable to detach membrane in the larynx and push it before the tube. To meet these results it might be said that theoretically tracheotomy could be resorted to secondarily, but practically it was then too late.

Tracheotomy permitted of the air being warmed and medicated, and of removal of obstructing exudate coming up into the trachea. It also permitted of carrying on nutrition perfectly, whereas, judging even by the statements of Dr. O'Dwyer himself, he inferred that the presence of the tube in the larynx caused considerable difficulty with feeding the child. It would seem, then, that the three points were met better by tracheotomy than by intubation. Whether these advantages of tracheotomy were real or imaginary could as yet hardly be determined by statistics. The difference in the character of the cases, and the fact that intubation was much more likely to be permitted than tracheotomy, formed the greatest obstacles in the way of a correct judgment.

He would accept Dr. O'Dwyer's personal experience with intubation without question, and among the first set of cases which he had reported twenty-four per cent. had recovered; later ones had given even a better result. Of 21,000 cases of tracheotomy collected by Lovett, twenty-eight per cent. had recovered. Dr. Pilcher's own results from tracheotomy for membranous laryngitis had been 22 recoveries out of 66 cases, or thirty-three and a third per cent. On the other hand, one of his neighbors had in-

tubated a number of cases and had fifty per cent. recover.

While he did not wish to gloss over the disadvantages attached to tracheotomy, yet he thought intubation answered the indications for surgical interference when the diphtheritic exudate had formed within the larynx and trachea much less perfectly than did tracheotomy, and that therefore, as a rule, it should not be considered a substitute for tracheotomy in such cases.

To What Extent has Intubation Supplanted Tracheotomy? — To this question Dr. Pilcher answered, evidently to a very considerable extent during the past few years in this country. Tracheotomy would always be accepted as a last resort unless it were in institutions, and he did not doubt but what for this reason intubation would save many lives which would without it be lost, parents rejecting what he regarded as the safer procedure until too late, if they permitted it at all. His neighbor had within four years intubated 140 cases, 40 of which, or twenty-nine and a half per cent. recovered, whereas Dr. Pilcher had had opportunity to tracheotomize only 66 cases in seventeen years, with recovery of one-third. Yet the cases of diphtheria in Brooklyn had remained about the same. This showed that intubation was both supplanting tracheotomy and also making a new field for itself. He thought there should be pavilions or houses scattered in different parts of the city, where diphtheritic cases could be readily transferred and put under skilled medical attendance, and as soon as the emergency arose a surgeon connected with the hospital of which these were a branch should be called to do tracheotomy. This would show better actual and comparative results for the bloody operation.

Dr. George W. Gay, of Boston, read a paper in continuation of the discussion. The statistics which he brought from the Boston City Hospital were later than those of Dr. Lovett, although they did not differ much; they showed about four per cent. in favor of the older operation.

In the majority of cases the result of intubation depended upon three conditions: laryngeal obstruction, bronchial croup, and septicæmia. The type of the disease, more than anything else, determined the result after the operation. In very many instances the operation was satisfactory although the result itself was fatal. The patient succumbed to sepsis or other trouble, but not to dyspnœa. In 110 cases at the Boston City Hospital in 75 intubation resulted in immediate and complete relief of the dyspnœa, partial relief in 22. Surely any method which gave immediate relief in nine cases out of ten was worthy consideration. As to whether tracheotomy would give relief where intubation failed, it might where the tube pushed membrane before it, enhancing the dyspnœa, but this accident was not common. But where the dyspnœa was due to extension of the morbid process or sepsis there was little hope. In fifty-eight cases of secondary tracheotomy at the Boston City Hospital, only seven recovered.

The author attributed many of the failures with intubation to employment by unskilled hands. He also said that the diminished number of tracheotomies at the Boston City Hospital and the much larger number of intubations showed that the latter had considerably supplanted the former. In the majority of cases in children under seven years intubation was preferable to tracheotomy.

Dr. F. E. Waxham, of Chicago, could not be present, and sent his recent statistics of intubation. He believed intubation would yield results which could not be obtained by tracheotomy. His cases were not selected, but included all requiring it which came under his observation. The number of cases for the several years of age were given, with percentage of recoveries. In all he had intubated 421 cases, with 146 recoveries, or 34.67 per cent. In the first 100 cases there had been 27 recoveries; in the second, 34 recoveries; in the third 40 recoveries, and in the last 21 cases there had been 7 recoveries.

Dr. A. Jacobi referred to a discussion on this subject before the Academy four or five years ago, at which it was all intubation, while to-night it had been part intubation and part tracheotomy. At the former meeting he endorsed intubation, notwithstanding the fact that he had been a pioneer in the performance of tracheotomy in this country, having resorted to it in a great many cases. Indeed, his statistics with tracheotomy must now run up to six hundred or seven hundred. The reason why he then and now endorsed intubation in preference to tracheotomy was the fact that it was very easy among the public at large to get permission to intubate, while it was very difficult to get permission to tracheotomize. Because of this difficulty the latter operation was often put off until it was known to be almost certainly too late. Yet now and then a case operated upon at so late a stage did recover, and it justified interference even in apparently hopeless cases. Another weighty reason for turning to intubation was the fact that, no matter what amount of care was exercised, infection and erysipelas or diphtheritic deposit might take place at the tracheotomy wound. Moreover, tracheotomy sometimes necessitated leaving the tube in a long time. While endorsing intubation, he confessed to not having performed it himself, for the reason that Drs. O'Dwyer, Huber, or others skilled in the operation had been within so convenient reach.

Dr. Francis Huber sent a note in which he said that both tracheotomy and intubation would relieve the dyspnœa, but after considerable experience with both measures he expressed preference for intubation as a primary procedure in laryngeal diphtheria. The mortality of either operation varied in different epidemics, the variations depending upon other conditions than the operation. Both procedures might present intrinsic difficulties in individual cases, and might be attended by unforeseen complications. Unfortunate results from inexperience and the use of improper instruments could not be placed as objections to intubation. The difficulties of technique in young children were not limited to intubation, but were often equally great in tracheotomy. Whatever might be the difference of opinion regarding the comparative results in older children, under two years and a half intubation gave a higher percentage of lives saved. He incidentally mentioned the great value of bichloride of mercury in diphtheria, as recommended by Dr. Jacobi.

Dr. Berg had performed intubation in a considerable number of cases, and in all it gave immediate relief to the dyspnœa, but the picture was apt to change within twenty-four hours. The following objections to the procedure had led him to practically abandon it: 1, Interference with feeding and nutrition, which was of such great importance; 2, interference with the administration of a solution of bichloride of mercury, as recommended by Dr. Jacobi, which also was of extreme importance, for, greatly to his surprise, he had found since adopting this treatment that its curative powers had been so great as to lessen the number of cases requiring intubation or tracheotomy fifty per cent. The bichloride, unfortunately, would act on the tube.

Dr. W. P. Northrup related some observations in Vienna and London during the past summer, illustrating the right and the wrong way of choosing tubes and introducing them into the larynx. He believed that, as a rule, difficulty from feeding the child wearing the laryngeal tube came from its unskilful introduction and injury to the parts.

One speaker said he had seen a number of patients wearing the laryngeal tube at the Willard Parker Hospital, and taking food without any difficulty, and that the house physician there employed irrigation with bichloride freely without causing any injury to the tube.

Another speaker thought the weakness following some hours after the introduction of the tube was due to inability to fully respire and finally complete stenosis and death. A second objection to the tube was the liability

to cough it up during the absence of the physician. He had lost one patient from that cause.

Dr. Johnson, of Jersey City, was not sure that where the tube was coughed up the cause was always membrane; nor did he think dyspnœa the usual cause of a change of the picture for the worse about twenty-four hours after introducing the tube.

After the discussion had been closed by the authors, the Academy listened to the report of the committee on conference with the Health Board, read by Dr. R. H. Derby. The report was approved and ordered published in the medical journals of the city.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, September 28, 1892.

J. S. Thacher, M.D., Vice-President, in the Chair.

Apoplexy of the Medulla Oblongata.—Dr. S. T. Armstrong exhibited a specimen of this condition. The patient, a man, fifty-four years of age, was admitted to the Harlem Hospital on September 22, 1892, having a family history which was negative as regards alcoholism and syphilis. He stated that he had been in good health up to September 1st, when he fell and fractured the tenth rib. With the exception of some pain on inspiration, he did not feel sick, and was able to continue at his work until the afternoon of the 15th, when he was suddenly seized with severe pain in the head, became dizzy, and staggered toward the sight side. With this there was numbness of the right side of the body and face, partial loss of power in the right arm and leg, and difficulty in swallowing, and from the onset of these symptoms he was troubled with insomnia. His condition remained much the same for the next three days, after which he was confined to bed. At the time of his admission, on the 22d of September, he was conscious, and able to give the history of his case. There was already motor paralysis of the right side of the body, and of the labial muscles on the left side of the face; on protruding the tongue it was deflected to the right; muscular and tactile senses were not affected, and the pupils were normal. There was great difficulty at this time in articulating and in deglutition; his pulse was 80, and his respirations 32 and somewhat labored. The urine contained albumin and a trace of sugar. When first seen by the speaker, on the day after admission, his condition was that described by the house-physician in the preceding history, and there was no special change until 1 A.M. on September 24th, when he became actively delirious, trying constantly to get out of bed, and when he did attempt to stand up he fell toward the right side. His pulse at this time was 85, the respirations 30, and the temperature normal. The pulse soon became rapid and irregular, the respirations slower, and at 5 A.M. he died of apnœa, the pulse continuing to beat for some time after the respirations had ceased.

At the autopsy the cerebral vessels were found to be congested, and there was a small hemorrhagic opening on the right side of the medulla oblongata, between the anterior pyramid and the olivary body. The roots of the ninth nerve were also seen to be involved. The floor of the ventricle was probably also implicated. The condition of the urine was probably due to an affection of the kidneys, but these organs had not yet been examined microscopically. Death resulted apparently from the gradual softening consequent upon the hemorrhage. These cases are quite rare, and therefore this one was deemed worthy the consideration of the Society.

Perforating Round Ulcer of the Stomach.—Dr. E. Hodenpyl presented such a specimen. The patient was a young woman, nineteen years of age, who, up to the time of her last illness, gave a negative family and personal history. She had enjoyed good health up to last June, at which time she began to suffer from sharp pains in the left hypochondrium. These were quite severe for two weeks, and continued with diminished severity for the greater part of the whole summer. Quite recently they again became more troublesome, and on September 6th, while going upstairs, she was suddenly seized with intense pain in this region, followed by vomiting and marked prostration. When admitted to the hospital, two days later, she presented the usual signs of general peritonitis, and she died six days after admission.

On opening the abdominal cavity at the autopsy the whole of the organs were concealed by a thick layer of fibrin and pus, which formed a sort of anterior cavity in the abdomen, which communicated with an opening in the stomach through which the contents of the stomach passed. The perforation was on the anterior wall of the stomach, near its middle, and measured two centimetres in diameter; the edges were perfectly round and smooth, the surrounding wall of the stomach was thickened, and the mucous membrane looked fairly normal. Near the œsophageal opening were small ulcers which involved only the mucous membrane.

A Specimen Showing the Result of Osteoclasis.—Dr. R. H. Sayre exhibited a specimen which had just been given him by Mr. Nicholas Grattan, of Cork, Ireland. It was removed from a child, about five years of age, upon whom he had performed osteoclasis for genu valgum about three or four months before the child died of a tubercular meningitis. The operation was done with Mr. Grattan's osteoclast. The specimen shows the changed direction of the femur, but there is no callus, and no irregularity of the bone, and were it not for a sharp twist in the outline of the bone, one would hardly notice that any violence had been done to it. The speaker said that he had operated with Mr. Grattan's osteoclast, and had noticed that the feeling of "the break" was peculiar; the sensation was as if the periosteum had not been torn, and something still held the broken fragments in position.

Dr. S. T. Armstrong said that an examination of the specimen made it doubtful if there had been anything more than a "green-stick" fracture produced at the operation.

Dr. Sayre replied that the click produced at the time of the fracture was so sharp and distinct that he was inclined to think that the instrument did really produce a complete fracture. He had never believed before this, however, that the periosteum was sufficiently elastic to remain intact under the application of such a force.

A Curious Anomaly of the Foot.—Dr. R. H. Sayre also presented a growth which he had removed from the foot of a child, and which resembled a thumb. On one foot there was an extra toe, between the big toe and the next one, and the end of the big toe was turned in almost at right angles with the other phalanges. On the other foot the small toes projected in various directions and were imperfectly provided with joints and nails. Instead of a large toe on this foot there was a digit, which in appearance and in the manner of its attachment resembled a thumb. It possessed an articulation like that of the thumb, and when the boy walked it was turned in under the sole. This "thumb" was removed by amputation.

Dr. Sayres also referred to a specimen which he had hoped to present. It was from a case of angular anchylosis of the knee-joint with subluxation backward. After chiselling the patella loose, it was found that the bones could not be replaced by any reasonable force. The joint was next opened, and it was then ascertained that the spine of the tibia had grown up into the intercondyloid notch of the femur, and projected about three-fourths of an inch. It was the first time that he had seen such a marked hypertrophy of this spine in any case on which he had performed resection.

The Society then went into executive session.

The Smallest Feet are said not to belong to the Chinese women but to those of Southern France. Cinderella was born in Avignon.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, October 17, 1892.

SAMUEL B. W. MCLEOD, M.D., PRESIDENT, IN THE CHAIR.

Cholera and Its Treatment.—DR. CHARLES A. LEALE read a paper, opening the discussion on this subject. He accepted the view held by competent judges that the cause was the comma bacillus; also that the disease originated in Hindoostan, and from there spread to other countries; but as to the origin of the first bacillus he knew as little as about the origin of the first of any other living thing. If filth was necessary to its continuous propagation, there was sufficient reason for its persistence in India. But, curiously, the disease died out in other countries within a few years after starting from India, whatever might be the condition of climate, filth, etc., in those other countries. The author thought it possible the germs were at times carried in great numbers and to great distances by wind-storms. He referred to some personal experience with cholera in this city. He had seen patients recover who had been in cramps three days, and others die within forty-eight hours. The cramps in the legs had best been overcome by compression-massage with the hand. If the physician saw the cases early during the premonitory stage, he could save nearly all. The first symptoms were abnormal secretion by the glands of the mouth and stomach, with disagreeable taste, nausea, and eructations of gas, then vomiting, then stomach cramps, then intestinal symptoms and passages.

In some cases, even of apparent death from rapid exhaustion, the patient could be revived by rubbing the blood toward the heart and applying heat. It was necessary in some cases to supply the blood with its lost constituents in order to save life. How could this be best accomplished? By the transfusion of blood or of any liquid into the veins? No, never! Most patients would be killed by the method itself. Should we try the introduction of any sterilized solution under the skin? No. There was a much simpler method. Nor should we give ice or drinks at a temperature much lower than the body. By the stomach or rectal tube one could easily flush the gastro intestinal tract with warm mutton-broth, or solution of sodium chloride, or egg albumin, enough of which would be absorbed to replace the lost constituents of the blood.

Conditions were mentioned under which cholera nostras might exist, even to the extent of misleading one to suppose there was an epidemic of Asiatic cholera.

The Choleriform Diarrhœa of Young Children; Its Differentiation from Asiatic Cholera.—DR. J. LEWIS SMITH read part of a paper in the course of which he touched upon the diagnosis between sporadic cholera infantum and Asiatic cholera in children. He thought little importance could be attached to the rice-colored stools in infants as pointing to Asiatic cholera. One must be guided largely by the fact whether cholera Asiatica was present in the vicinity; then, also, cholera infantum was ordinarily a disease of the hot months. Both affections might be of bacterial origin, but the comma bacillus which was the cause of Asiatic cholera was not the cause of cholera infantum. Careful autopsies justified the statement that cholera infantum was a most severe gastro-intestinal catarrh. There was a consensus of opinion, he believed, that it was not contagious.

The Bacteriological Diagnosis in Cases of Cholera in New York.—DR. EDWARD K. DUNHAM illustrated on the screen and under the microscope the comma bacillus as cultivated from the recent cases of cholera in this city, and contrasted its appearance and behavior with those of some other germs.

The Probable Advantages of Quarantine, and the Proper Methods of Conducting it.—DR. JOHN GODFREY, of the United States Marine Hospital Service, in discussing this subject, said he would make only a few general remarks. He was one who believed in positive advantages of quarantine. There were also disadvantages. He quoted a British sanitarian who had said that we knew not what was the cause of certain diseases against which it had been attempted to establish quarantine, and therefore confidence could not be placed in quarantine measures for keeping them out; that if the country were kept in a proper sanitary state quarantine would not be necessary. It was because of this uncertainty of opinion as to the spread of disease that methods of quarantine and prevention in general differed. The first necessity in establishing an effective quarantine was to convince everybody of its utility; then we might hope for the proper method of conducting it. Quarantine could be enforced in one of two ways: 1. By killing the germs before they entered the country. 2. By non-intercourse with countries where cholera existed. Or what might be called a compromise between the two methods might be adopted. In order to cope with an enemy successfully one must know his weapon; must know his vulnerability. Without such knowledge he could not proceed scientifically. Regarding cholera, science might perhaps talk ex-cathedra, but regarding some other diseases against which we established quarantine, science could not thus speak. Who could say, for instance, that bichloride, instead of killing and keeping out germs of yellow fever, did not in reality invigorate them? Let not science attempt to say steps had been taken which would keep out a contagious disease, unless it were known to be a fact.

Speaking of what commerce would say, Dr. Godfrey thought that a quarantine which would prevent epidemics without stopping the wheels of commerce was an ideal quarantine, but which was yet to come. It was a question of dollars and cents on one hand and of human life on the other. Those who should argue for quick commerce, although it should result in the death of a few of the steerage passengers, might prefer to have all the commerce of the world destroyed rather than lose one of their own family by a disease which could have been prevented.

Dr. Godfrey's view of a proper quarantine system implied an efficient officer who was a bacteriologist and scientist; whose position did not depend upon a political pull; a laboratory fitted with all necessary appliances; sufficient skilled help.

The Pan-American Medical Congress and Its Influence on Sanitation and Quarantine.—DR. WILLIAM PEPPER, of Philadelphia, President of the Pan-American Medical Congress, impressed the benefits to accrue from such a congress, particularly in relation to prevention of spread of epidemic diseases between the several ports and countries of North and South America, and to showing our southern neighbors the facilities here for medical education and literature. At this congress not only cholera, but also yellow fever, would receive consideration.

DR. STERNBERG being called upon, referred to the work done regarding quarantine at the International Medical Congress held in Rome. He had long been an advocate of a national quarantine system; had long been of the opinion that it was not right for the health of the whole country to be in the hands of one State. He believed national quarantine should be maintained at national expense. He also thought it was a great imposition upon shippers of commerce that they should bear the whole expense, instead of all those who were benefited by commerce. He ridiculed the farce of disinfection for a fee.

DR. GIHON said that in the navy they kept cholera out by rigorously excluding any possible medium of bringing it on board, and should it manage to enter they rigorously isolated the patient and carried out disinfection. He thought that was all that could be done at any quarantine establishment. It was a mistake to place dependence on local sanitation for prevention of spread of cholera. Cellars remained dirty and unventilated in American cities, no matter what outward cleanliness was apparent. Supplementary of what Dr. Pepper had said regarding

the Pan-American Medical Congress, he urged upon all who could do so to attend the meeting of the American Public Health Association to be held in Mexico.

Dr. Nye suggested that they send medical missionaries over to Asia, where cholera was endemic, and have them clean up.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MR. HUTCHINSON ON NAMES, DEFINITIONS, AND CLASSIFICATIONS IN DISEASE—SIR WILLIAM SAVORY ON SYMPTOMS IN PERSPECTIVE—INTESTINAL OBSTRUCTION WITH THROMBOSIS OF ABDOMINAL AORTA—NÆVUS OF PERITONEUM—MYXŒDEMA SUCCESSFULLY TREATED BY INJECTIONS OF FRESH THYROID JUICE.

London, October 22, 1892.

Among recent medical utterances Mr. Hutchinson's Presidential Address to the Medical Society of London deserves a foremost place. It was delivered last Monday evening at the opening meeting of the Society for the present session. Mr. Hutchinson said there was need for a large reform in medical nomenclature, for better classification of disease, and, above all, for more precise definitions of the terms used. As soon as the physician or surgeon tried to get out of routine, he felt himself cramped and hindered by our narrow and conventional systems of nomenclature and our fragmentary classifications. He would ask the neurologist whether such names as tabes dorsalis and epilepsy did not now each include a number of separate maladies which required separate grouping. He would ask the physician whether he was content with the terms "diabetes" and "hysteria," while respecting dermatology he would venture to offer his own opinion that there were at least twenty maladies classed under the name of lupus which required to be discriminated, and, putting all these aside, some five or six different types of "tuberculosis of the skin." Names, definitions, and classifications were far more difficult in our department of natural observation than in any other. The clumsy expressions "substantive disease" and "morbid entity" were probably in use among us far oftener than sound knowledge of the facts would justify. A distinction must be drawn between a description and a definition. The former took cognizance of the outward appearances of the disease described, and might be developed in much detail; the latter should be concise, and should exclude all that was extraneous.

He would take the names of three common diseases—phagedæna, erysipelas, diphtheria—and try to define them, and at the same time to show how their definitions affected their position in any system of classification founded on natural affinities. Phagedæna, it might be said, was not the name for a disease, but rather for a certain condition occasionally assumed by the inflammatory process. He would assume that there was no difference of kind, but only of severity, between simple phagedæna, sloughing phagedæna, and hospital gangrene. It was also exceedingly probable that noma and cancrum oris were really of a closely similar nature, though of a more severe type, with the phagedæna so often encountered in syphilis. Granting these data, we had first to note that it was undoubted that cancrum oris, noma, and syphilitic phagedæna might begin quite independently of contagion.

It was, therefore, not a specific malady in the sense of being dependent upon the implantation of a specific virus. We must next record that, although these inflammations might occur to persons seemingly in robust health, they were almost invariably those who had suffered from syphilis or, in the case of noma and its congener, recently passed through a specific fever. We might also assert, but with more hesitation, that the use of mercury had often preceded not only the syphilitic forms, but also those seen in children. We came, then, to the definition of phagedæna as a locally destructive form of inflammation, which attacked sores and wounds, which varied much in severity in different cases, and which occurred for the most part in those who had recently suffered from some specific disease. To this must be added the important proposition that, although capable of spontaneous origin under the conditions mentioned, it was infective to adjacent parts, and might become contagious to other patients with open wounds. Phagedæna was not to rank with the specific fevers, though it might become epidemic. It was a type form of specialized inflammation, occurring under certain known conditions of predisposition.

Mr. Hutchinson then discussed erysipelas and said he came to the conclusion that this was a name for a form of inflammation presenting peculiar features, very infectious to the tissues of the patient, easily spreading to the wounds of others, and of which one attack left proclivity to a second. We had to add to this—unless we insisted that medical and traumatic erysipelas were two different things—that it was capable of origin from exposure to cold and without either wound or contagion. This definition placed it by the side of phagedæna, and just as it would be more correct to speak of phagedænic inflammation than of phagedæna, so it would be better to use the expression "erysipelatous inflammation" rather than erysipelas, since the latter was too suggestive of a substantive disease which always ran the same course and always presented the same conditions.

The facts as to diphtheria were exactly parallel with those as to erysipelas and phagedæna. All three occurred sporadically and in connection with individual proclivity rather than specific influences, yet all might become contagious, prevail as epidemics, and when they did so they kept close to the type. Diphtheritis was probably a more correct term. What was there to hinder us from defining this as a contagious inflammation of mucous surfaces, and chiefly of the throat, frequently attended by the formation of pellicles, infective by continuity in the patient, and easily spreading by contagion to others? It was wrong to make the formation of the false membrane a part of the definition, for that was to make the diagnosis of a disease depend, not upon its origin, but upon the degree of severity with which it developed certain peculiar phenomena which were common, but not invariable. He felt sure he should be criticised for not admitting to a foremost place in the definition of such affections as diphtheritic and erysipelatous inflammation the parasitic microbes which had been demonstrated to be usually present. While fully admitting their importance he was yet not convinced that they constituted the disease. The rôle of the bacillus in leprosy was far from being established, while it would be very premature to define any one form of lupus as being the product of the bacillus of tubercle. If we do so, we should at once have on our hands a number of closely cognate maladies which could not be so explained, and which it would yet be impossible to put wholly aside. In the disease known as rhinoscleroma the presence of a microbe had been demonstrated only in a few instances.

New names should be short and easily remembered, should be in the vernacular, should be available from the very beginning and such as the the observer himself might without indecorum apply, and should have in themselves no meaning, the reader being left to find that out by reference to the writings of the observer who first applied the names. These conditions excluded the use of the discoverer's name, which Mr. Hutchinson deprecated on other grounds also, though he remarked that such names, being meaningless so far as etymology went, had the negative advantage that they did not mislead. Narrating an anecdote told him by Dr. Billings, of a layman who had suggested that it would be more fair that a disease should be named after the patient, Mr. Hutchinson remarked that he had long adopted the plan though he never used the real name in public. Probably many of

as already did this in private. The present plan of making a small number of names suffice for a vast number of objects, and of slavishly grouping together under the same name diseases which differed widely, was one which had encumbered us too long. There was probably no better plan in aid of exactitude in clinical observation than to take "type cases," to follow them to their end, describe them in detail, and, wherever possible, to illustrate them by photography, or by drawings. By the side of the type case place all others which really fitted with it and none others. Anyone adopting this plan would be surprised to find how rapidly parallel cases of what he at first thought rare and exceptianal would accumulate. We were all too prone to diagnose (that was, to name) first and to observe afterward. To make a diagnosis ought to mean to recognize, so far as was possible, the real nature of a disease; it was too generally used as if it meant to give a name.

Mr. Hutchinson concluded his address with a few words about classification. Taking dermatology as an example, he asked whether it was not possible to attempt something in the way of a natural classification of skin diseases which should be of the utmost value to the student? He thought it most desirable that there be a classification of skin diseases according to their natural affinities. We could not assign at once all maladies to their proper place, but this was not requisite.

Sir William Savory gave an interesting address on Thursday evening to the members of the North London Medical and Chirurgical Society, on "Symptoms in Perspective." Each of the symptoms in a given case, he said, was to be regarded not so much in its absolute value as in its relative significance. The true meaning of a particular sign was only to be reached by considering it in relation to the rest. No doubt a single symptom might have a value which outweighed all the others. What the rules of perspective were to the artist the sound knowledge of the relative proportion of symptoms was in surgical diagnosis. He quoted numerous illustrations of the relative value of symptoms. In cases of calculus of the bladder the frequent presence of blood in the urine, he said, had a much higher diagnostic value than abnormal frequency of micturition. In the diagnosis of fracture of neck of the femur shortening was of more importance than eversion, and as evidence of acute inflammation rise of temperature was far more trustworthy than pain. Everyone knew, too, that the diagnosis of a case usually depended on an assemblage of symptoms, no one of which might be in itself strong, but which in conjunction with others might mean much. For example, neither a rigor nor an attack of sweating, nor a rise of temperature, by itself or in association with certain other symptoms, might be significant of septicæmia, but a rigor followed by profuse sweating and associated with a high temperature, occurring for the first time at a certain period after the infliction of a wound, was indeed very strong evidence of the occurrence of blood-poisoning.

The surgeon stood on firm ground in the presence of objective symptoms, but if so assured he came to neglect the subjective ones he might be led into serious error. In illustration of this Sir William Savory related the case of a man who had suffered from gout in the form of phlebitis and in other ways, and who gradually became jaundiced, while a tumor, which everyone recognized as a distended gall-bladder, presented itself. Weakness and emaciation increased but his chief complaint was of constant, dull, but severe pain in the back. The case seemed tolerably clear to most who saw it, and more than once it was proposed to open the gall-bladder. The patient died without an operation and advanced malignant disease of the pancreas was found; no disease of the liver was present, and only a few calculi in the gall-bladder, none of which were impacted. The objective symptoms were so marked that they and the persistent pain in the back were referred to a common cause which was believed to be confined to the region of the liver.

The first meetings of the Clinical and Pathological Societies have also just been held. At the former society, Mr. W. H. Brown, of Leeds, read notes of a case of intestinal obstruction, ending fatally, from gangrene of the lower limbs; after death, a thrombus was found in the abdominal aorta, plugging that vessel and extending down the iliac vessels. Mr. Arbuthnot Lane related a case of extensive nævus of the peritoneum in a boy of seven, which was successfully removed by operation. At the Pathological Society, Mr. Hurry Fenwick showed two female patients suffering from myxœdema, in whom injections of fresh thyroid juice had been followed by improvement.

INTESTINAL SUTURES.

To the Editor of the Medical Record.

Sir: In the Medical Record for September 17, 1892, I noticed an article on a new method of circular enterorrhaphy by Dr. M. E. Connell, of Milwaukee, Wis. I have experimented on over two hundred and twenty-five dogs for the purpose of trying all kinds of sutures and plates in intestinal operations. The form of suture which Dr. Connell reports, I have used in fact many times. But I never used it as a single continuous suture all around the circumference of the gut without interruption by tying. I would run the suture continuous for three to five stitches, and then tie. I have several times used the Lembert suture continuous around the gut, and tied it where it originally started.

But my results were not so good, for the reason that the suture always fell into the gut-lumen, and the threads act as distinct paths to conduct infection into the peritoneal cavity. The suture will slowly and gradually come away, and all the time it is falling into the gut-lumen a part of the suture is dangling into the fecal current, where innumerable vegetable germs live and thrive. More than once, in autopsies on dogs, I have seen where these sutures are fastened to the gut-wall and dangling in the fecal current, making a distinct invasion into the gut-wall. This hole in the gut-wall was distinctly made by infection travelling along the suture. In such cases many times only the graft saved the dog's life. It threw out an exudate as the infection advanced, and the exudate from gut and graft frequently succeeded in stopping the gut-hole. Again, the suture is dangerous by capillary attraction, for where fluids can travel germs can likely go. But if the suture were interrupted every three to five stitches and tied, I found it acted in a safer manner. In a continuous suture all around the gut there is danger of some of the stitches becoming loose or too slack by doubling of the gut-wall or contractions of the muscles in the wall through peristalsis. An accidental passage of hard fæces might loosen one or two sutures by irregular pressure. Again, to stitch the two ends of the gut as Dr. Connell does, with a continuous suture, has in my experiments invited the formation of fecal fistulæ. So I always strengthened such sutures with a Lembert which was continuous for three to five and then tied. The sutures in "plates," it is true, penetrate the whole gut-wall, but fecal fistula does not follow, because the plates hold in continuous and fixed coaptation the serous surfaces of the gut, and a fistula is almost impossible on account of the accompanying exudate encapsulating the invading wound. But I found, if I did not use more than the form of suture recommended by Dr. Connell, that danger followed more frequently than when I used the addition of a few Lembert sutures.

The method I follow now to do a circular enterorrhaphy (excluding the stove-pipe and invagination [without sutures] operations), is to entirely sever the gut and introduce a rubber tube four to six inches long into the proximal end of the gut. The rubber tube must be much smaller than the gut-lumen. It would be better to introduce more than one rubber tube in a gut with a large lumen. The tube is sewed to the proximal end of the

gut, so as to retain it for four to six days in a fixed position. The object of the rubber tube is to prevent invagination subsequent to operation. The invagination may occur months after the operation. I lost four per cent. from this cause. Three-fourths of the tube should project into the proximal gut, and the remainder of the rubber tube is thrust into the distal gut. I now unite the circumferences of the distal and proximal bowels by a "baseball suture," *i.e.*, a continuous suture all around the gut which penetrates the entire intestinal coat (mucous membrane, muscular wall, and peritoneum). This suture unites the tightest and closest with the least employment of gut-wall to invert and evert. The inversion or eversion of the gut circumference is what aids in producing stenosis of the gut-lumen. I now use Lembert sutures which are interrupted every three to five stitches and tied. Scarification and a graft (severed or unsevered from the omentum) completes the operation. I am continually operating on dogs' intestines in giving courses to practitioners, and we make careful autopsies on the dogs which die, and also those which we kill after the operation to observe the results; and so far as I can judge, the safe suture in intestinal surgery, in circular enterorrhaphy, is first, the Czerny suture. This suture should penetrate the whole gut-wall, and it is best done in the form of the "baseball" suture. This suture prevents immediate leakage of the fecal contents.

The second safe and reliable suture is the Lembert suture, which can be made continuous for three to five stitches, and then interrupted and tied. Wholly continuous sutures around the entire gut circumferences invite fecal fistula, and set up the dreaded triumvirate of abdominal surgery—pain, tympanites, and vomiting. I congratulate Dr. Connell on his new method of experimenting, and hope it will prove better in other hands than it has in mine.

Respectfully,

FRED. BYRON ROBINSON, M.D.

34 WORTHINGTON STREET, CHICAGO, ILL.

Erysipelas	0	0
Leprosy	0	0

The Offspring of Mulattoes.—Observations extending over a period of thirty years concerning the morbid proclivities of mulattoes are embodied in a paper by Dr. W. A. Dixon, in the *Medical News*, August 13, 1892. Living close to the boundary separating the old slave States from free States, the author has had peculiar facilities for studying his subject at length. Fifty years ago and more, it was the custom of wealthy planters, as they advanced toward age, to liberate such portions of their "estate" that bore to them a filial relationship, and establish these in homes in localities where good treatment, consideration, and respect due to citizens could be secured. Thus in Southern Ohio there grew up a community of mulattoes, the offspring of white men of wealth and position, who themselves represented the best New England stock. These pure mulattoes were tall, muscular, well-developed, complete types of physical perfection, many living to old age, sometimes to one hundred years. Proud of their parentage and light skin, they took for wives women who were also half white. Prosperity and pride held them aloof from the negroes. Their children intermarried, and their race continued until the fourth generation, when these families gradually became extinct. The offspring of the first cross were robust; those of the second paler, more ash-like in complexion, slight in figure, evincing predisposition to, and characteristics of, tubercular disease; while in the second and third generations of pure mulatto intermixture all the children were girls and notably sterile. The fourth generation proved even less fertile, and presented cutaneous affections, ophthalmia, rachitis, hydrocephalus, hip and knee-joint disease, and various glandular abnormities.

These facts would seem to prove the affirmation of ethnologists, that human hybridity cannot be maintained without reversion or fresh supply from parent blood. Such a type can only have an ephemeral existence. In the second and third generation of pure mulatto blood the offspring were inferior in vitality and intelligence, and consequent morality. Their churches, independent school-houses, their very names, in time, disappeared. Some form of tuberculosis gradually undermined and extinguished them. The statement is made that when purity of race is maintained in civilized or barbarous countries, there is but little or no tuberculosis. And the dismal suggestion of ethnologists, cited by Broca, is given in full, to make us shudder or pause, according to temperament, to wit, "that the United States, where the Anglo-Saxon race is still predominant, but which is overrun by immigrants of various other races, is by that very circumstance threatened with decay, inasmuch as their continuous immigration may have the effect of producing a hybrid race containing the germ of disease, degeneration, and future sterility." The writer of the paper forcibly remarks that it is wise as well as necessary to look beyond the bacillus for causes resulting in tuberculosis, crime, idiocy, and insanity. Purity of race is one safeguard against constitutional inferiority that brings with it lessened mental and moral vigor.

Miss Kilmansegg and Her Aluminium Leg.—An exchange says that aluminium is to be used in the construction of artificial limbs, a use to which it seems to be particularly well adapted, owing to its great strength and lightness.

Tooth Culture.—In an address on "Tooth Culture," delivered at the annual meeting of the Eastern Counties Branch of the British Dental Association, Sir James Crichton-Browne referred to a change which has taken place in bread as one of the causes of the increase of dental caries. So far as our own country is concerned, this is essentially an age of white bread and fine flour, and it is an age, therefore, in which we are no longer partaking, to anything like the same amount that our ancestors did, of the bran or husky parts of wheat, and so are deprived to a large degree of a chemical element which they contain—namely, fluorine. The late Dr. George Wilson showed that fluorine is more widely distributed in nature than was before his time supposed; but still, as he pointed out, it is but sparingly present where it does occur, and the only channels by which it can apparently find its way into the animal economy are through the siliceous stems of grasses and the outer husks of grain, in which it exists in comparative abundance. Analysis has proved that the enamel of the teeth contains more fluorine, in the form of fluoride of calcium, than any other part of the body, and fluorine might, indeed, be regarded as the characteristic chemical constituent of this structure, the hardest of all animal tissue, and containing 95.5 per cent. of salts, against 72 per cent. in the dentine. As this is so, it is clear that a supply of fluorine, while the development of the teeth is proceeding, is essential to the proper formation of the enamel, and that any deficiency

in this respect must result in thin and inferior enamel. Sir James Crichton-Browne thinks it well worthy of consideration whether the reintroduction into our diet of a supply of fluorine in some suitable natural form—and what form, he asks, can be more suitable than that in which it exists in the pellicles of our grain stuffs?—might not do something to fortify the teeth of the next generation.—*Dental Register.*

A New Pasteur Institute.—The Mayor recently laid the corner-stone of the New York Bacteriological Institute which Dr. Gibier is building at Ninety-seventh Street and Central Park West. The building will be 26 x 95 feet, and five stories high, with a basement. It is hoped to have it completed by next January. The free treatment of persons suffering from rabies will be continued in the new institute, although it is from the treatment of private patients that the expenses of the bacteriological department will be met.

Insuring Against a Sudden Increase in the Family.—A company has recently been organized in London, the ostensible object of which is to insure married people against twins and triplets. A married man expecting to become a father must deposit £5 to become a policy-holder. In case the policy-holder's wife has twins he will receive £50; in case she has triplets, £75. The company is called the "Provident Bounty Association." It has issued a prospectus calling attention to its conditions of issuing policies, which it says are simple and are intended to appeal especially to the lower middle class, including young bookkeepers, shop clerks, and small tradesmen.

Something Like an Empty Honor.—The office of Surgeon to the Queen in Ireland has been offered to, and accepted by, Sir William Stokes. The vacancy was caused by the death of Mr. William Colles, and the appointment of Sir William Stokes has received hearty approval as being well merited. As, however, the Queen will never go to Ireland, Sir William is not likely to find his time much taken up with operations on Her Majesty.

The Eliminative Value of the Sweat in Infectious Diseases.—Brunner asserts that pathogenic microbes are in part eliminated by means of the sweat. His investigations to determine this point were met with the difficulty that it is not easy to sterilize the skin so as to be sure that the micro-organisms found in the secretion were derived from the tissues and fluids of the body, and not from its cutaneous surface. This obstacle was, however, overcome by using animals which had been inoculated with disease, the pathogenic organism of which could not accidentally have been lodged on the skin. The animal was then made to perspire profusely, and further inoculation and cultivation experiments were made with the sweat. A culture of staphylococcus aureus was injected into a hog, one of anthrax into a cat, and one of micrococcus prodigiosus into a sucking-pig. In all three cases the microbes injected were found in the sweat, and also in the saliva. This property of the perspiration, if it be a constant one, would give to crises, accompanied by profuse perspirations, a more important place than they have hitherto held. It would also show that there may be great danger in allowing a patient who has been sweating profusely to reabsorb the secretion.

The Painlessness of Death.—A writer in the *Pall Mall Gazette* has given an account of his sensations while dying. He fell under the ice while skating, and when brought out by some others who had seen him disappear, was seemingly dead, and was resuscitated with great difficulty. In describing his sensations while dying, he says: "I gasped and swallowed a great deal of water. I felt my lungs filling. A moment of suspense, during which I knew perfectly well I was drowning, intervened; and then—I died. I was drowned and dead. Just before I died, however, I noticed—deliberately noticed, for I am pyschological by nature—that my whole past life did not come up, as I had been given to understand it would, in a single flash before me. . . . The knowledge that I have thus once experienced in my own person exactly what death is, and tried it fully, has had a great deal to do, I think, with my utter physical indifference to it. I know how it feels, and, though it is momentarily uncomfortable, it isn't half so bad as breaking your arm or having a tooth drawn. In fact, the actual dying itself, as dying, is quite painless; as painless as falling asleep."

Cremation in England.—The conversion to cremation as a form of sepulture in this country is slow, although progress appears to be being made. According to the latest report, in 1885, when the Woking Crematorium was instituted, only three bodies were sent, in 1886 ten, in 1887 thirteen, in 1888 twenty-eight, in 1889 forty-six, in 1890 fifty, and in 1891 ninety-nine. Thus every year has shown a slow but steady progress. The charge at Woking is five guineas, including the services of an attendant, use of chapel and waiting-room, and an urn for the preservation of the ashes. The railway company's charges are an extra, and the local clergyman's fee is a guinea if the burial party does not provide its own cleric. The ashes can be either buried in the grounds at a fee of one guinea, or preserved in the chapel of the crematorium, or they may be taken away. Two medical certificates are required to show cause of death, and one, at least, of the doctors giving such a certificate, must have attended the deceased in the usual manner; it must also be stated that the deceased has expressed no wish contrary to the carrying out of this form of burial. It usually takes about an hour and a half to cremate the body, and the process must be performed three days after death took place in London, or four days in the country.—London Correspondence of the *American Practitioner and News.*

Remarkable Condescension on the Part of Royalty.—The *Hospital* gravely announces that "Her Majesty has graciously consented to accept the right of placing a child in the Merchant Seamen's Orphan Asylum, Snaresbrook, and has intimated that it may be known as 'The Queen's Presentation.'"

SOME PRACTICAL POINTS IN THE DIAGNOSIS OF SPINAL-CORD LESIONS.

By FREDERICK PETERSON, M.D.,

CHIEF OF CLINIC, DEPARTMENT FOR NERVOUS DISEASES, VANDERBILT CLINIC, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

THE spinal cord, while it is a sort of cable carrying messages to and fro between the brain and the periphery, is at the same time to be regarded as a series of thirty-one segments, piled one upon the other, each segment connected with a pair of spinal nerves, and each being a trophic, reflex, and vaso-motor centre. These thirty one segments occupy only seventeen or eighteen inches of the spinal canal, which is twenty-six to twenty-eight inches long. Hence, while the first segment of the cord is at the foramen magnum, the thirty-first (or conus) is found opposite the base of the first lumbar vertebra. If one takes a cosmetic pencil it is very easy to draw, on a thin person, an outline of the spinal cord upon the back over the vertebral column, and in this way one gains a clearer knowledge of these puzzling relations than by any amount of reading. The eighth cervical and first dorsal segments are just in front of the spine of the seventh vertebra.

The lumbo-sacral enlargement of the cord begins immediately in front of the tip of the spine of the tenth dorsal vertebra; the conus is just in front of the lower point of the first lumbar spine. Below this point the canal is filled with the cauda equina (lumbar and sacral nerves).

The most important parts of the spinal cord, from a pathological point of view, are the cervical and lumbar portions, or enlargements, for there is an intumescence of the cord in each of these regions, due to the fact that the sensory, motor, and trophic centres for the arms and hands are in the one, and those for the legs (as well as the reflex centres for the bladder, rectum, and sexual organs) in the other.

The cord consists of "columns" of white matter surrounding the H-shaped central gray. The "columns," or tracts, contain the long fibres, which transmit peripheral and central impresses and are variously named, as in the diagram (see Fig. 1). The reflex, trophic, and vaso-motor centres are wholly in the gray matter of the cord. The spinal-cord should be regarded, moreover, as consisting of two symmetrical halves, like the brain, with sensory fibres decussating the whole length of the cord, and fibres uniting anterior columns and anterior horns of opposite sides.

There are diseases which attack certain columns, or certain parts of the gray matter, and these are termed system-diseases. The pathological processes are localized in the parts figured in Fig. 2. These "system-diseases," such as polio-myelitis, progressive muscular atrophy, amytrophic lateral sclerosis, lateral sclerosis, ataxic paraplegia, and locomotor ataxia, are readily recognized by the peculiar symptoms brought about by injury to certain systems of fibres or cells. This localization is quickly seen in the pathological picture presented above.

But the so-called "focal" diseases of the spinal cord, lesions of limited extent in a particular segment or segments due to tumors, pressure, hemorrhages, inflammations, spinal injuries, and the like, are not so readily localized, for the symptoms—reflex, trophic, sensory, and motor—are extremely variable, depending as they do upon the segment-level of the pathological process. As regards reflexes, those of the rectum and bladder are abolished by lesion in the fourth and fifth sacral segments and the conus of the cord; ankle-clonus in the fifth lumbar; the knee-jerk in the third lumbar; the wrist and elbow-jerk in the sixth cervical, and so on.

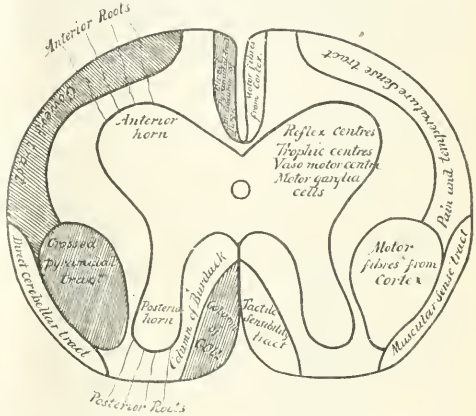

FIG. 1.—Diagram of Transverse Section of the Cord, showing Anatomical Topography on the Left, and Physiological Functions on the Right Side.

Motor and trophic disorders are also distributed in the same manner, segmentally: so that, for instance, muscles of the toes are represented in the first and second sacral segments, of knee flexors in the fourth and fifth lumbar, thigh muscles in the second and third lumbar, abdominal and spinal muscles in the second to twelfth dorsal, thumb

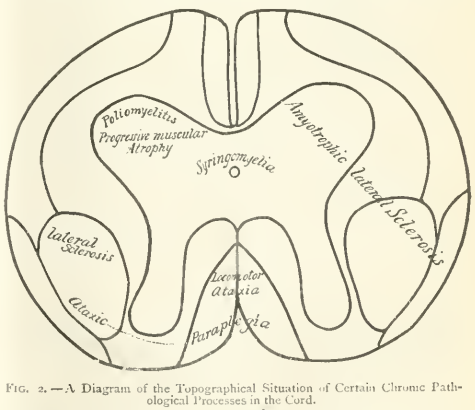

FIG. 2.—A Diagram of the Topographical Situation of Certain Chronic Pathological Processes in the Cord.

and fingers in the eight cervical and first dorsal, forearm in the sixth and seventh cervical, shoulder in the fourth and fifth, neck in the second and third—and so on, this representation being in regular order "lowest muscles in the lowest segments." The sensory distribution is also segmental, but has peculiarities of great diagnostic value. Thus

anæsthesia of the perineum, scrotum, rectum, vagina, and posterior surface of penis is produced by a lesion in the lowest part of the spinal cord, viz., in the fourth and fifth sacral segments and conus. If the lesion is higher, say at the third sacral segment, the anæsthesia extends farther out on the buttocks and down the backs of the thighs—over the parts, in fact, which touch a saddle in riding (so-called "saddle-shaped" area). If the lesion be at the fifth lumbar, the anæsthesia includes the outer sides of both legs, and even the outer edges of the feet at times. Now, in order to render all of these facts much clearer than could be accomplished by mere description, I have made two drawings of the most important parts of the spinal cord, from a localization point of view, founded upon the excellent clinical papers of Starr, Herter, Thorburn, and Mills. These parts are the cervical (Fig. 3) and lumbar (Fig. 4) enlargements, and upon the segments are mapped out (in large type vertically) the reflex centres; the names of muscles are written in their proper segments and the areas of anæsthesia, according to the seat of any

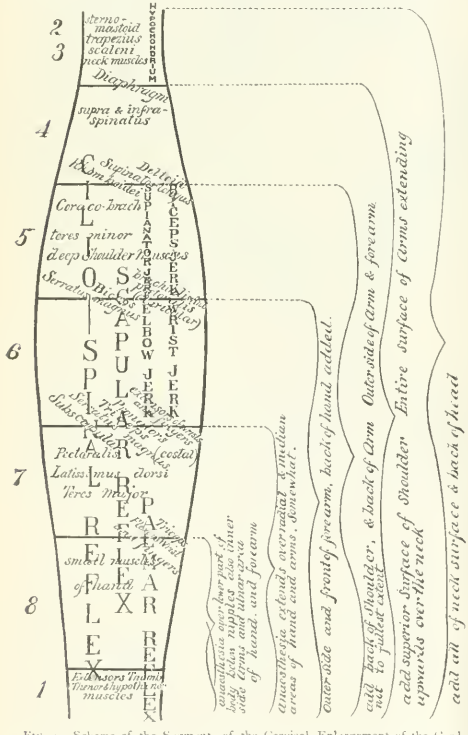

Fig. 3.—Scheme of the Segments of the Cervical Enlargement of the Cord, showing the Reflex Centres, Segmental Representation of Muscles, and, to the Right, the Extent of Anæsthesia produced by Destructive Lesion at Various Levels.

transverse lesion, are shown at the side. I have found these pictures very valuable for reference and to help the memory, and I trust they will be lucid and helpful to students and general practitioners for whose benefit they are published. In lumbo sacral localization there are two important diagnostic points which we owe to Starr, viz.: 1. In hysterical anæsthesia the anus, genitals, and perineum remain sensitive. 2. Cauda lesions high up are distinguished from destructive lumbo-sacral lesions by comparatively extensive paralyses when sensation is but slightly affected.

There are chronic lesions in the central gray matter of the cord, such as syringo-myelia, which produce peculiar symptoms according to the segmental level of the lesion. Encroaching on the gray matter of the anterior horns, of course, the particular muscles of that segment are paralyzed and atrophied, and lose their reflex excitability. Encroaching around the central canal and toward the posterior horns, a peculiar anæsthesia is produced to pain and temperature, distributed, of course, according to the particular representations of skin area at the level of the

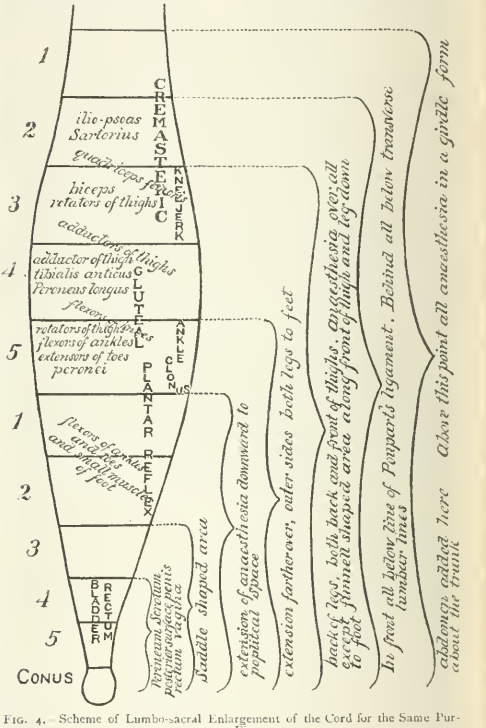

Fig. 4.—Scheme of Lumbo-sacral Enlargement of the Cord for the Same Purpose as Fig. 3.

lesion. This is because the fibres for pain and temperature sensibility lie in the central gray matter before entering their tract on the periphery of the cord (see Fig. 1) to reach the brain.

Lesions of the motor tracts in the white matter of the lateral and anterior columns produce muscular weakness, or paresis, but without atrophy. This paralysis is naturally much more widespread than the paralysis caused by injury to the anterior horn. For instance, a very small lesion, say the size of a pea, in a lateral column will probably affect all of the muscles on the same side below that point, the lateral tract being the cable containing nearly all of the long fibres of communication between one side of the body and one-half of the brain. On the other hand, the same lesion in an anterior horn would produce a very restricted paralysis, affecting only the muscles innervated from that particular segment.

Another feature peculiar to paresis from lateral-column injuries is the spastic rigidity with exaggerated tendon reflexes; and still another important point for differential diagnosis is the loss of faradic reaction in paralysis, due to lesion in the anterior horn or motor nerve, and the perfectly normal reaction of these muscles to faradism when the paralysis is due to lesion in the long fibres running from the cortex down the lateral and anterior columns to terminate in the large cells of the anterior horns.

Hence there are four absolutely opposite clinical conditions or symptoms which will serve to differentiate for

us the two distinct types of spinal paralysis, the atrophic and the spastic; and these may be conveniently grouped as follows:

Atrophic Spinal Paralysis.	*Spastic Spinal Paralysis.*
1. Atrophy.	1. No atrophy.
2. Lost reflexes (such as knee-jerk, wrist-jerk, elbow-jerk, etc.).	2. Exaggerated reflexes.
3. Flabby relaxed muscles.	3. Rigid muscles.
4. No contraction to faradism. Lesion in the anterior horns.	4. Contraction to faradism. Lesion in the lateral columns.

This calls to mind the importance of a complete understanding of the knee-jerk by the general practitioner.

It is of the highest value among the reflex symptoms. The tap upon the tendon sends a sensory impulse to the reflex centre in the anterior horn of the third lumbar segment (*via*, the sensory nerve from the knee-area and posterior root and posterior horn), whence an impulse is reflected outward (*via* anterior root and motor nerve) to contract the quadriceps extensor. While the knee-jerk is, in truth, not a perfect representation of an actual reflex, yet for all practical purposes it may be so considered. Now, certain fibres from the cortex pass down by way of the lateral columns of the cord to enter the anterior horns, and these hold a rein upon the reflexes, so to say. They inhibit the jerk. Thus, under normal conditions, the knee-jerk is very moderate. If this inhibitory fibre is functionally impaired or destroyed the knee-jerk is no longer restrained but becomes exaggerated. If any part of the reflex arc is destroyed (sensory nerve, posterior

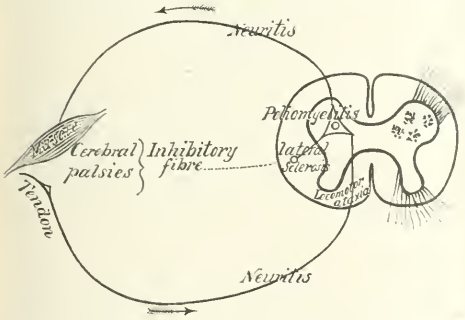

Fig. 5.—Diagram, showing Reflex Arc and Inhibitory Fibre, and some of the Diseases which Exaggerate or Destroy the Knee-jerk.

nerve-roots, posterior root-zone, posterior horn, anterior horn, or motor nerve) the knee-jerk is lost. Thus cerebral palsies, lateral sclerosis exaggerate the knee-jerk; whereas neuritis, locomotor ataxia, polio-myelitis, and the like, destroy the knee-jerk. Fig. 5 is offered as a diagrammatic illustration of these points.

In lesions affecting the inhibitory fibres anywhere all the tendon reflexes below the lesions become exaggerated. Thus ankle-clonus, not normally present in anybody, develops where the lateral column is affected above its centre in the fifth lumbar segment.

A unilateral lesion of the spinal cord gives rise to an interesting syndrome, generally termed Brown-Séquard's paralysis. Suppose that one lateral half of a segment of the mid-dorsal region were destroyed, the result, seen in a typical case some time after the injury, would be:

Same Side.	*Opposite Side.*
1. Atrophic paralysis of muscles innervated by that particular half-segment.	1. Loss of pain, temperature, and touch-sense below the lesion
2. Spastic paralysis of the leg.	
3. Lost or impaired muscular sense.	
4. Exaggerated knee-jerk, and usually ankle-clonus.	
5. At about the level of the lesion a half-girdle of hyperalgesia, and just below this a parallel zone of anæsthesia.	

The wrist-jerk, under normal conditions rarely present, or just perceptible, becomes very excessive in lesions of the cerebro-spinal segment of the motor tract above its special centre in the sixth cervical segment.

In the earliest stage of an acute unilateral lesion the knee-jerk may be absent for a short time, which is also true of both knee-jerks in any complete transverse lesion of the cord above the third lumbar segment, but subsequently it takes on its over-active character.

The reason that muscular sense is impaired on the same side is that the fibres for muscular sense do not decussate along the spinal cord as do the other sensory fibres.

TRAUMATIC INJURIES TO THE EYE.[1]

By G. H. COCKS, M.D.,

Assistant Surgeon to the New York Eye and Ear Infirmary, Attending Physician to the Institution of Mercy, etc., New York.

Mr. President and Members of the Harlem Medical Association: The title of my paper, "Traumatic Injuries to the Eye," includes injury to the conjunctiva, cornea, sclera, iris, lens, etc. If one receives a blow upon the eye from a stick of wood, the fist of an antagonist, chips from steel or stone, the injury inflicted will depend upon the size of the object, and the force with which it is propelled.

Commencing from without, we first meet with injury to the conjunctiva. This membrane is very tolerant of other than chemical injuries and may be incised in operations, or extensively lacerated, without danger of serious consequences. Should the wound be extensive, it can be closed with fine sutures, but even this is not always necessary.

After operations for pterygium or the removal of small tumors the parts can be left to heal, but the final result is better if the conjunctiva is loosened from the eyeball on each side of the wound and the edges brought together with fine sutures. If, however, the injury is produced by lime, strong acids, or burns of any kind, the contiguous portions of palpebral and ocular conjunctiva are most likely to unite and severe deformity result. A case of mine, hod carrier by trade, had some lime strike the eye between the cornea and inner canthus. I did not see him until several weeks after the accident. At that time he was greatly annoyed, as he could not see well to walk the beams. The scar resulting from the burn had drawn the pupil so far inward that he could not carry it outward, even to the median line. On this account he could not calculate the distance of objects to the outer side of him, and was very apt to fall between the beams while at his work. I removed the cicatrix, and by loosening the conjunctiva and bringing in a flap he was able, after the wound had healed, to carry the pupil a little to the outer side of the median line.

It is found necessary, quite often, in these cases, to insert conjunctiva from a rabbit's eye, to take the place of the cicatricial conjunctiva. I have seen Dr. H. D. Noyes operate in this manner several times. The operation is by no means a simple one, but the result is often quite gratifying.

Wounds of the conjunctiva from small particles, such as cinders from the elevated roads or small fragments of wood, often produced serious trouble.

If a patient comes to you complaining of a scratching sensation in the eye, especially if it has come on suddenly, do not dismiss him until you have made a thorough examination of the under surface of each lid, as well as in the cul-de-sac of the upper lid. On everting the upper lid you are very apt to find the offending particle there. If you do not find it, have him look downward as far as he can. This act will expose the conjunctiva of the cul-de-sac, and sometimes the foreign body.

One of the members of the New York Ophthalmological Society mentioned a case, several years ago, of a

[1] Read before the Harlem Medical Association, February 3, 1892.

young man who complained of something irritating his eye. He had been to several physicians, but had not received any satisfactory relief. The narrator, not finding any trouble of the lids to account for the suffering had the patient look as far downward as possible. He did as directed, and the surgeon was much pleased to see a small shot dislodged from its hiding-place in the cul-de-sac.

A lady patient came to me about ten days after her right eye first became inflamed. The lids were swollen, and an apparent catarrhal inflammation was in progress. The inflammation, to my surprise, did not yield readily to the usual treatment. Two weeks later the patient brought a very small splinter of wood to my office. She said the night before, while bathing the eye, she felt a sharp pain, and while she continued to bathe the eye this small piece of wood had come out. She then recalled that several days previous to her eye becoming inflamed there was smoke in the room; opening the oven door, a gust of smoke blew into her face. The husband had placed some damp wood in the oven without informing his wife. The wood became charred, and this small piece had been driven under the lid by the force of the escaping smoke, and lodged in the cul-de-sac.

Gunpowder appears to be remarkably non-irritating to the conjunctiva. After the inflammation resulting from the explosion *per se* has subsided the grains of powder will remain for years without causing inflammation. They are removed most frequently for cosmetic purposes. The grain of powder is seized with a mouse toothed forceps and is removed with the conjunctiva in which it is embedded. This leaves a small wound which usually heals very kindly.

In contused wounds we quite frequently find a large subconjunctival hemorrhage. When such a case presents itself we take his vision, and if it is not as good as the uninjured eye an ophthalmoscopic examination should be made to determine whether any deeper tunic, or the vitreous or lens is involved. If the vision is good we can calm the patient's fears by informing him that no serious injury has been produced and that in from one to five weeks his eye will be all right.

The Sclera.—This is not so frequently injured as the cornea, as its firm structure gives it great resisting power. When, however, the sclera is injured the traumatism which produced it is usually so severe that we have very little hopes of preserving useful vision. The complications which may exist are in great measure dependent on the force of the blow and the extent to which iris, lens, or vitreous have been injured at the time of the accident.

Simple incised wounds, in which none of the underlying structures are involved, heal kindly. Sometimes it is necessary to unite the edges with a suture. Care should be exercised so as not to pass the suture entirely through, but just far enough to get a bite.

In punctured wounds the vitreous not infrequently escapes through the wound. If the wound is not large, the "bead" of vitreous should be cut off with a pair of sharp curved scissors. The eye should be thoroughly washed and a light bandage applied. The patient should then be put to bed and the eye watched carefully. If the instrument which produced the puncture can be removed the prognosis is much better than if produced by a shot or small object that cannot be extracted.

Rupture of the sclera may be produced by the cork from a champagne or soda-water bottle, sticks, toy-arrows, by the fist of an antagonist, a missile thrown by another, etc.

I have now under my care a man, aged forty, who, while walking in the street, was struck just below the lower lid of the right eye with a stone. The injury consisted of a lacerated wound just below the lid and a complete rupture of the sclera upward and inward. I saw him about three hours after the injury. On opening the lids I found the lens lying between them. All the vitreous had escaped, leaving the eye a shrunken mass.

Prognosis in rupture of the sclera is not always bad. Dr. H. D. Noyes mentions a case where the rupture occurred in such a position that the iris was removed *in toto* without disturbing the lens.

A wound in the region where the union of sclera and cornea occurs almost always involves the ciliary region. This is a most unfortunate accident, as very slight injury to this part is so frequently followed by disastrous results. If the wound be so severe that the underlying tissues protrude, they should be cut off, the wound cleaned of all foreign substances, and, if not too extensive, the edges can be brought together with sutures. Strict antisepsis should be followed in treating all wounds of the globe.

I have the pleasure of presenting, for the benefit of the members, a patient who received a severe injury to both eyes by the explosion of a disconnected gas-meter. The patient was examining the number of the meter as it stood on the floor alongside of several others that had been removed the same day. He struck a match, and as he brought it close to the face of the meter an explosion occurred. His face was bleeding from many small wounds when he walked into my office a short time after the accident. I removed many small pieces and one large piece of glass from face and forehead. Examining the eyes I found a wound at the sclera corneal margin inward in the right eye. I examined closely but could detect no glass in the wound. The cornea of left eye was injured in several places. Downward and inward there appeared to be a perforating wound. On using the ophthalmoscope, I found a very slight opacity of lens.

I mention this case at this time to call attention more particularly to the injury to the right eye. As the inflammatory swelling subsided a piece of glass was seen imbedded in the iris, its edge just beneath the cornea.

January 1, 1891.—Fifteen days after the injury the V. in O. D. was $\frac{1}{2}\frac{7}{0}$; in O. S. $= \frac{1}{4}\frac{5}{0}$.

The question arose whether to remove the foreign body, or "let well enough alone." I asked the advice of two of the surgeons at the New York Eye and Ear Infirmary, and they both decided it was best to wait, especially as he lived in the city and could seek medical aid early if trouble should arise. He has called on me about once a month since the accident. I have examined and find very little change since the subsidence of the inflammation.

The Cornea.—This is so prominent that it is frequently the recipient of slight as well as severe traumatism. Its clearness and regular curvature are so important to perfect vision that even slight traumatism may produce severe impairment of vision.

In New York City the most common injury to the cornea is produced by cinders, sparks of steel, small particles from emery wheel, chips from stone and chisel. In the country and in farming districts the burr from grain often produces disastrous inflammation.

Not infrequently the mother receives an injury to the cornea while playing with the baby. In throwing its arms about, the finger-nail removes the epithelium from the cornea. The injury to the cornea is usually slight, but the pain is frequently intense. In these cases a few drops of the four per cent. solution of cocaine will relieve the pain. The eye should then be lightly bandaged to prevent the light striking the exposed and irritated cornea and the lids from rubbing against the wounds.

Cocaine has been a great boon to those unfortunates who have been injured by what we commonly call foreign bodies on the cornea. Previous to its discovery we found it necessary to place the patient's head against our breast, hold the eye steady by pressing the index and middle fingers of the left hand against the globe, while the right hand was free to use the spud or needle. The pain produced, as any one who has had a cinder deeply imbedded in the cornea removed can testify, is very severe. It required not a little skill to remove quickly and thoroughly a small cinder in those days, but now that is changed. Under the influence of a four per cent. solution of cocaine the patient will permit prolonged manipulations without evincing any discomfort.

With this drug in the hands of the general practitioner it is not necessary to send every case of foreign body on the cornea to the specialist for removal. This does not mean that the eye will stand any more abuse while under the influence of cocaine than it did before; but that under its influence the patient will allow you to work directly on the spot of impingement instead of all sides of it, as not infrequently happened before the use of cocaine.

In the case of cinders it becomes necessary not only to remove them but the scale produced by their contact with the cornea.

At the New York Eye and Ear Infirmary I have seen not a few cases where the foreign body in the cornea has been removed by the "expert" at the shop or factory, but the scale has been left. This is just as irritating as the body itself, and *is* a foreign body. To remove it a sharp needle is often required. So far I have referred only to those cases where the foreign body in the cornea is in the superficial layers of the cornea. Where the foreign body has passed nearly through the cornea, just short of perforation, its removal is no easy matter. In these cases it sometimes becomes necessary to introduce a long narrow-bladed knife into the anterior chamber and press the body forward while it is seized in front with a pair of forceps.

The burrs from grain often produce severe damage when they strike the cornea. Occasionally they perforate the cornea. When this occurs severe inflammatory action is set up, the cornea becomes hazy at the site of perforation, and if not controlled an ulcer with hypopyon will be the result. In these cases, after the burr has been removed, hot boracic acid solution should be used, together with atropia, two grains to the ounce three times a day. If the hypopyon is not absorbed it then becomes necessary to open the anterior chamber and evacuate it. The hot-water treatment with atropia should be continued, and sustaining measures adopted.

To detect small and fine particles on the cornea a biconvex lens of about two inches focus is required. Dr. H. D. Noyes has an arrangement by which the lens is held on the index finger of the left hand. This permits one to focus the light better than the lens in the hands of an assistant. It also enables one to do without an assistant. With small and nervous children it sometimes becomes necessary to give chloroform, as the sight of an instrument produces such a nervous state that you cannot approach them. If you attempt to hold their eye by force they will jump at an unexpected movement and perhaps cause you to produce severe damage.

Incised and Perforating Wounds of the Cornea.—If the incision is produced by a perfectly clean knife, as in the extraction of cataract, all that is necessary is to apply a light bandage so that the lids do not move over the incision; the aqueous soon accumulates, the anterior chamber is re-established, and in a few days firm union has occurred. Where the wound has been produced by a non-aseptic instrument it then becomes necessary to thoroughly cleanse the eye with an antiseptic solution, such as boracic acid, free the edges from all extraneous substances, then close the lids, having previously instilled a few drops of atropine if the wound is central, or eserine if near the periphery of the cornea.

In those cases where the wound has perforated the cornea the aqueous escapes, allowing the iris to fall against or pass through the incision. If the wound is recent an attempt should be made to replace the iris, but if this is firmly bound it will be necessary to seize the iris and cut it off with a pair of curved scissors. If the wound is firmly united it is better to reopen it and perform iridectomy, as the constant tension upon the iris is prone to produce inflammation.

Iris.—This stands traumatic injuries remarkably, providing the instruments are aseptic. In the extraction of cataract, with iridectomy, the iris is withdrawn from the anterior chamber and a large piece removed, yet iritis of a severe kind very rarely follows. In extraction without iridectomy, which has been performed so much of late years, the iris is pressed upon by the lens as it escapes through the pupil, yet iritis is not a frequent sequence. Out of 109 cases operated on at the New York Eye and Ear Infirmary in 1889 only 34 had iritis follow, and this of a mild character.

Foreign bodies in the iris produce, in the great majority of cases, very severe inflammation. Occasionally, however, foreign bodies remain for many years implanted in the iris without causing destructive inflammation. Mr. D——, the patient mentioned before in this paper, has now a piece of glass in the iris of right eye that has caused but slight trouble since its lodgement there in December, 1890.

Dr. Noyes mentions a case where a piece of iron has remained innocuous for nineteen years. In the treatment of such a case we are governed by the character of the patient and his accessibility to good surgical help in case of trouble.

When a case of traumatism first presents itself, especially if immediately after the accident, it is not always easy to determine the presence of a foreign body on account of the hemorrhage that so frequently occurs in these cases. If they have waited several days, and remark, when asked why they did not come at once, "Oh, Doctor, I thought it would be nothing!" we often find the anterior chamber filled with blood, the tension of the eye increased if the chambers have been refilled with aqueous, and the patient suffering intense pain. We cannot see the foreign body on account of the hemorrhage and chemosis. It is necessary in these cases to employ antiphlogistic measures until the inflammation has subsided and then treat the condition found.

If the patient presents himself immediately after the accident, and the foreign body can be seen, it should be removed at once. If a few cases have carried a foreign body in their iris for years, the majority have not. We can offer no guarantee that the eye will remain quiet, but, on the other hand, can say that its presence is a constant menace, and with but slight provocation will set up an inflammation that may involve its fellow.

To remove a foreign body from the iris is not always easy. If the body be a piece of iron or steel, a strong magnet will sometimes remove it without the necessity of performing iridectomy. If, however, the bit of iron is caught in the tissue it will not yield to the magnet unless near it or in actual contact (Noyes). Dr. Gruening employs a cluster of permanently magnetized steel rods. I have seen this used with success, but in one case of my own I did not succeed.

For the purpose of removing the foreign body, or rather introducing forceps, the strength of which should correspond to the size of the foreign body and the existing adhesions, the original wound may sometimes be utilized, even though it be closed, and it may be opened again and enlarged according to the exigencies of the case. It is usually necessary to open the chamber by a new incision with a cataract or lance-shaped knife. Peripheral incisions extending into the scleral border are usually to be preferred, especially if the knife can thus be pushed partially or wholly behind the foreign body. It must not be forgotten, however, that prolapse of the iris follows more readily in such wounds, if they exceed one-quarter of the corneal circumference, and thus excision of the iris may become necessary on this account. In other cases a wound made in the centre of the cornea is better, or only adapted for the seizure and extraction of the foreign body. "Care should be taken in selecting the location, direction, and size of the incision, in order that the undisturbed foreign body may be seized most conveniently and firmly with the forceps, and that when the preservation of the iris, and especially the capsule of lens is concerned, the removal of the foreign body may be accomplished without much turning or twisting" (Arlt of Vienna).

Traumatic iritis may be produced by disease of the eye

itself, irrespective of outside influence. It may be produced by keratitis, cyclitis, and injuries and dislocation of the lens. Soft lens matter after extraction may cause it.

On January 14th I saw a case of dislocation into the anterior chamber. The lens had been there but a short time, yet iritis had developed. An operation for the removal of the lens was advised, but the patient did not appear at the time appointed.

After cataract extraction, especially without iridectomy, if the cornea fails to heal promptly and the iris protrudes through the corneal section, in this case it is generally necessary to perform iridectomy. In a recent case at the New York Eye and Ear Infirmary Dr. Dennet removed the lens of the left eye without iridectomy; the result was perfect. Three weeks later he operated on the right eye without iridectomy; but two days later the iris prolapsed and iridectomy was resorted to.

If soft lens matter is the cause of an iritis after extraction, it becomes necessary frequently to reopen the corneal incision and remove it.

In iridectomy, if the edge of the iris becomes incarcerated in the wound, iritis usually results. If the incarceration is extensive it must be relieved.

Traumatic cataract may be produced by an injury that does not injure the globe directly or cause laceration of the capsule, the snap of a whip-lash, cork forced from a bottle, or it may be produced by any object lacerating the capsule of the lens. Foreign bodies not infrequently penetrate the cornea and lodge in the lens or its capsule. Sometimes the patient suddenly moving while a paracentesis of the cornea is being performed the capsule may be injured and thus cause traumatic cataract. The result of the capsular lesion is to cause the lens to swell by the imbibition of the aqueous, transforming the transparent lens into a white or bluish white mass. If the wound of the capsule is large, soft lens matter exudes and is often thoroughly absorbed by the aqueous, leaving a clear pupil. If the lens swells too quickly and the aqueous does not accumulate, the lens falls forward, the iris is pressed upon, a severe iritis is set up, and sometimes irido-cyclitis of so severe a type that the eye is destroyed. Occasionally small particles have been caught in the capsule and have remained quiet, producing no further trouble than a slight opacity, for years.

Traumatic cataract develops within a few hours, or days, or weeks. It exhibits a great variety of conditions according to its cause. According to the degree to which the capsule has been lacerated will be the extent and rapidity of the swelling and the irritation of the eye.

I have now under my care an Italian who received a severe injury after an explosion of gunpowder. The left eye is the worse. Here we have a fairly good picture of the effect of such an injury. The cornea has numerous opacities, but the lens has been severely damaged. The iris is attached to the anterior capsule so firmly that nothing short of surgical interference will relieve it.

The treatment of these cases varies with the condition found. Sometimes the lens is entirely absorbed. If the foreign body is steel or iron the magnet introduced through the wound will sometimes remove it. We thus get rid of the cause, but not so readily the effect. The eye should be kept quiet and atropine used to prevent adhesions. If the lens becomes solid it may be removed, providing we feel that fair vision can be obtained.

We have now to consider those cases where more than one, or many of the parts of the globe are injured. If the globe is severely lacerated so that lens and vitreous have escaped, and the eyeball has collapsed, the quickest way to rapid recovery is enucleation or evisceration. It is wonderful, however, with what tenacity of purpose these cases will hold on to an eye that is positively destroyed. If a foreign body has penetrated the globe, many complications present themselves, and just what is best to do is not always easy to determine. The amount of injury already inflicted, the position and nature of the foreign body will help us greatly to decide what is best.

At the clinic, January 28, 1892, a young boy presented himself for treatment of a little scratch on the cornea. On asking him how it was produced he answered that while working with chisel and hammer on iron the previous day a small chip of iron struck him in the eye and fell out again.

I examined the eye by oblique illumination without atropine and saw a slight scratch on the cornea. The eye was but slightly injected and there was no pain. It appeared to be a very fortunate case. For fear something more might have happened than appeared at this examination I put a few drops of atropine in his eye and then with the ophthalmoscope a very pretty cataract was seen. The case then developed into a very interesting one. The question arose as to whether the foreign body was still in the eye. He was examined by a number of competent men. One felt very positive that he could see it imbedded in the sclera, but none of the others could find it.

Minute fragments of metal, as in this case, leave very slight trace of entrance, especially in the sclera. On examining the interior of the eye we can sometimes find them sticking in the lens, suspended in the vitreous, or imbedded in the sclera. If the object is larger much hemorrhage is apt to result, so that the ophthalmoscope is of no service. Bird-shot may enter and leave a slight wound behind. There was the case of a boy who received an injury from bird-shot thrown by a "bean-shooter" in the hands of a playmate. When the boy presented himself for treatment severe iritis had set in, and the ciliary region was so involved that enucleation was determined upon. Enucleation was performed and the bird-shot found within the eye.

Prognosis is always bad. If the injured eye alone was only to be considered we would not feel so worried as to the result. But the fellow eye so frequently becomes influenced by a slow and subtle process, especially if the injury be in the ciliary region.

There are exceptional cases, where the foreign body has remained harmless for many years, but such good fortune occurs but rarely. "The size, the situation, the nature of the foreign body and the amount of harm inflicted give us the elements of prognosis" (Noyes).

As regards treatment, the indications are to removal, as any foreign body within the eye is very prone to produce not only inflammation in it, but also its fellow. Many of these accidents are caused by pieces of steel or other metal that can be attracted by the magnet. A sufficiently large enough opening is required so as not to strike the fragment off as it is being withdrawn on the magnet. When the chip of iron has entered the vitreous the magnet is of especial value. Sight is not always saved but the globe is often preserved. If, after careful search, the magnet fails to bring out the iron, enucleation must be resorted to. Dr. Noyes mentions an interesting case in this connection. A man came under his care who three months before had received a bit of iron in the globe, and the eye had recovered. A second fragment penetrated the same eye, and he proposed to remove both with the magnet, and operated with the understanding that if two bits of iron were obtained the eyeball should be spared; if only one or none should be gotten, enucleation should ensue. This course was taken because the eye was certain to be sightless and extremely prone to cause sympathetic inflammation. One small particle was brought out and diligent fishing failed to get the other, and the eye was taken out. Only after a long search was the second fragment found sticking in the optic papilla. It was covered by exudation and so well concealed that there was strong reason for belief that this was the first piece which had entered the eye, and a three months' residence in the head of the optic nerve had not given rise to any symptoms in either eye. The piece was found by using the magnet as a searcher, as the half of the globe floated in water and was attracted to the magnet.

We cannot guarantee success in this any more than

any other severe surgical operation. We do, however, preserve useful vision to many. In a few, a low grade of inflammation is set up which causes the eye to shrink. If the eye is not saved, sympathetic trouble surely results. If the patient refuses an operation the danger he runs should be clearly stated. A few weeks after the injury the eye may look very well and the patient will congratulate himself on not submitting to the advice of the doctor. A few more weeks, perhaps months, will pass. Then he notices a slight redness "around the sight," the eye becomes painful to the touch. He is very much surprised to find he cannot see so well with the sound eye. After a little longer delay he again seeks the advice of the surgeon, but, alas! too late. Sympathetic inflammation has set in. He now consents to enucleation, but, sad to relate, the inflammation does not subside after the removal and he is doomed to total darkness.

I will close by quoting a sentence from Dr. Noyes's late work: "One of the greatest triumphs of the oculist is when he discriminates correctly the dangers of an injured eye and by skilful treatment and wise forbearance preserves to the patient his precious possession of sight or eyeball."

ARTERIAL SALINE INFUSION; A REPORT OF THREE ADDITIONAL CASES BY THE NEW TECHNIQUE.

By ROBERT H. M. DAWBARN, M.D.,

PROFESSOR OF OPERATIVE SURGERY, NEW YORK POLYCLINIC.

In the MEDICAL RECORD of January 2, 1892, and again in the *Brooklyn Medical Journal* for October, 1892, the writer described a new and entirely simple method of saline infusion, which in severe cases of hemorrhage, of shock, and of cholera, seems destined to replace the former cumbersome plan of using a scalpel, searching for a collapsed vein, and tying therein a cannula for injection.

That plan is the insertion of a hypodermatic needle into the common femoral artery, and through this injecting the salt-water, by an ordinary Davidson syringe, directly into the circulation. In cases not almost moribund, the same device is to be used; but now the fluid is thrown simply into subcutaneous cellular tissues instead of into the artery.

Also the writer urged, upon physiological grounds, that the salt-water used should be very hot, not less than 120° F., or as warm as the hand can possibly bear. It was shown that no harm could result from even nearly 40° F. hotter than this; and on the contrary, the stimulant effect of the hot water upon the heart, and also upon the unstriped muscular tunic of the vessels, in restoring their lost "tone," was almost magical; as demonstrated by various experiments at that time detailed.

In addition to reports of experiments upon dogs by this new plan in the College of Physicians and Surgeons laboratory, a case was published in the MEDICAL RECORD wherein the patient—moribund from post-partal hemorrhage—was resuscitated by the intra-arterial salt-water infusion, and recovered.

The only objection (a self-evident one) to the device, is the hesitancy naturally felt to pierce so large an artery; and this vanishes when one reflects that the most prominent plan now used by surgeons for aneurisms so placed as to be inoperable by ligation, and yet threatening rupture, is that of Macewen, of Glasgow; which is needling, and in which long needles are thrust—a dozen or so—into the sac, and left for many hours, to cause thicker deposits on the walls—and this with benefit, as a rule.

If a diseased vessel can safely stand such treatment as this, it seems a mild inference that a sound artery can bear a single needle for a single half-hour. And such has been my experience so far.

Of course, if our patient be not too perilously weak, the salt-water may simply be thrown into the cellular spaces beneath the skin, and diffused by rubbing. Also a warm saline enema should be given in either instance. But in critical cases no one should trust to these plans alone, but all would prefer to make sure that the heart and blood-vessels get the benefit of the injection; and here the practitioner must choose between the old and cumbersome, and the new and simple.

How many family doctors will actually, think you, take out their unaccustomed scalpel in such cases, hunt up that cannula which must be tied in, and then incise and search for the collapsed vein? Echo does not answer.

I verily believe that many a patient has died from bleeding, of one or another origin, who could easily have been saved by the simple plan of arterial infusion which the writer has devised, and that many such will be rescued thereby.

All that we need will be always readily at hand: 1. A hypodermatic needle—largest size preferred. 2. A Davidson syringe, from which the usual nozzle of metal or vulcanite rubber is removed. 3. Boiled water (for aseptic reasons), hot as hand can support, plus a heaped teaspoonful of table-salt.

Never omit the salt—it would be fatal to mix plain water with the blood, as this at once dissolves out the hæmoglobin from the blood-disks; whereas even so small an amount of salt as that named—six parts per thousand—renders it safe, and, for practical purposes, seems as good as the most complicated saline-alkaline formula possible.

I need hardly add here that blood transfusion, either mediate or immediate, has now been dropped by almost all surgeons.

When a person has bled to death, half his blood (roughly estimated) still remains in his body; and if this is properly increased in bulk by an innocent fluid, this added bulk is all that the heart needs to make it resume work. The remaining blood-cells support life until nature increases their number again, which is done with almost magical speed.

As to the amount of salt-water needed: Here let me say that while a pint at a time is enough within the artery, the operator cannot seriously err on the side of throwing too much into the subcutaneous connective tissues. Almost always the mistake is made of injecting less than half the right amount—which is usually at least two quarts; and a gallon would do no serious harm if properly distributed in a dozen or more spots. The half-filled arteries of hemorrhage or shock, or the thickened blood of cholera, will promptly use what is needed. If there be an excess over this amount, in a few hours to a day or so, it will gradually be taken up from the connective tissue, meanwhile doing no harm, and the kidneys will dispose of it.

The doctor makes the mistake indicated (of using too little saline infusion under the skin), because he estimates only the actual blood lost in a hemorrhage, and seeks simply to replace this same bulk of fluid. He forgets that because of shock (caused by that bleeding), the vessels have lost their "tone" and are almost completely dilated. The patient has bled into his own veins as well, and the brain and heart are made doubly anæmic thereby. Remember, the abdominal veins alone are capable, when paralyzed, of holding all the blood in the body.

For the benefit of those who did not read the original article in the MEDICAL RECORD, it may not be amiss to repeat the technique of arterial infusion.

The Davidson syringe, needle, and hot salt-water being ready, the operator now feels, just beneath the middle of Poupart's ligament, for the femoral artery, here large enough in calibre to carry a lead-pencil. If the heart is still beating, this great pulse can almost always be felt. The aspirating needle is now forced gently and directly into the artery, entering it at right angles; not with a sudden plunge, but by a slow, rotary movement. As soon as the point is within the lumen, bright-red blood will fill

the needle instantly; whereupon it is held very firmly and steadily in place while an assistant slips over the base of the needle the end of the syringe, already filled, and ties it in place with a thread. The solution is now thrown into the arterial current steadily, and necessarily slowly, which last is an added point in favor of this plan. It takes about one-half hour for a pint to enter.

If the subject be very fat, an aspirating needle is preferable to the hypodermatic, which would here be too short to be held in place steadily; though, indeed, lacking the former long needle, a simple incision through the fat may be made, enabling one to approach the vessel more nearly and readily with the fingers.

The Davidson syringe, if old, should be disinfected by pumping boiling water through it before use. If leaky, hold the bulb, and the hand working it, beneath the salt-water, to avoid throwing in air. To maintain the temperature at about 120° F. the bowl containing the solution should be placed in a larger one, holding much hotter water. In this wise, by adding from time to time to the heat of the outer bowl or pan, that of the inner vessel may easily be kept as hot as the hand can bear. As soon as the circulation seems improved somewhat, the subcutaneous method of infusion should supplant the arterial.

In my original article on this subject the technique included the use of a soft-rubber (Nélaton) catheter, to connect needle with syringe. Added experience proves this unnecessary, and it is accordingly dropped.

I have now to report four new cases of saline infusion, in three of which the arterial method was used.

Case I.—Mrs. R——, a patient of Dr. Charles S. Collins, of this city. She was shot just above the left kneecap some days previous to the date of operation. Every symptom pointed to septic infection of the joint, and the patient's general condition was of the worst. Her pulse was feeble, her temperature high, her system shattered from hard drinking. In fact, her husband, for a long time previously, had refused to live with her because of her drunkenness.

Operation on February 4, 1892, Drs. F. J. Brockway and C. S. Collins assisting. The bullet was found embedded in the femur and removed. The joint was distinctly purulent; it was washed out and a half-dozen drainage-tubes inserted where most needed. The patient, simple and brief as was the operation, and almost bloodless, was now in collapse. She presented every evidence of extreme and acute shock, threatening death almost at once. The pulse was 160 to 170, and almost too thready to be counted. Strychnine and strophanthus and whiskey by needle were employed; also a hot enema containing whiskey, and all the usual methods. These not causing rallying, the case seemed to me to call for saline arterial infusion at once. Because of shock the patient was bleeding into her own veins, if I may so phrase it. In fact, I may remark that a certain distinct, severe, and acute type of shock so closely resembles concealed hemorrhage as to be practically undistinguishable from it; and, indeed, the treatment of each should be identical. It is well known that gynecologists now suspect a slipped ligature, and reopen the abdomen, where a few years ago the patient believed to have "shock" was allowed to die unaided, while the open vessel steadily drained away her life-blood.

I am a believer in preventing shock, if possible, rather than treating that grim and deadly enemy after it has our patient in its grip. At present the best single drug for this purpose is strychnine. When shock is already present it may wisely, if cautiously, be carried to the point of producing moderate tetanism; and under its use the pulse, in favorable cases, falls in frequency and rises in strength. But why, if this be a fact, may we not wisely give it in fairly full doses for a few days before our operation, as a preventive?

And why would it not be wise, at the end of any and every operation grave enough to make shock a probable result (though because of the ether not yet at hand), to inject subcutaneously a quart or two of hot salt-water? It would be painless, the patient not yet being out of anæsthesia. It would certainly be harmless. And I believe it would do much to prevent, by maintaining filled blood-vessels, an otherwise fatal shock from developing. I believe we shall ultimately see this done as a matter of invariable routine after all severe operations.

This digression may be pardoned me when we reflect that less advance has been made of late years in our treatment of shock than in any other subject of prime importance in surgery.

To return to our patient. The hypodermatic needle was inserted in her right femoral artery, the vessel being found at the first attempt. A pint of hot saline solution was thrown in by the fountain syringe—which plan I do not like, both because it is impracticable in rooms with low ceilings, and because it is impossible to maintain so well thereby, as by the Davidson syringe and two dishes, an evenly hot temperature in the infusion fluid. Following this first pint, about three pints more were injected, this time into the subcutaneous spaces; and the lumps (eight or ten) so produced on the thighs were diffused by rubbing with the vaselined hand.

The woman steadily revived. Her heart-beats slowly but regularly decreased in frequency. Dr. Collins remained by her side several hours. At length her pulse fell to a trifle under one hundred, and as it was also good in quality, he took his departure feeling that she was out of danger and could safely be left a short time. Before going he expressly warned her to lie absolutely quiet. No sooner had he gone than she demanded whiskey. This was produced by a relative. She sat up to drink it—and dropped back dead.

I think it will be admitted that this woman would probably have recovered had she obeyed orders, thus avoiding this sudden strain on her heart.

Case II.—Mrs. D——, seen on June 28, 1892. This patient was one in whom the hemorrhage was due to placenta prævia. She was attended by Dr. J. Milton Mabbott, of this city, who called me in to use saline infusion, because in his judgment her circulation was so bad as to require it. The bleeding which followed delivery had ceased by the time of my arrival. I found the lady pale and covered with cold sweat, restless in the extreme, delirious, asking for air—in a word presenting the usual, and some unusual, signs of anæmia; but as her pulse was not extremely and critically bad, I proposed to inject the salt-water simply subcutaneously.

Dr. Arnold Burkelman was also present, and asked me to use the intra-arterial technique, as he had never seen it. This I accordingly did, the needle entering the artery at the first attempt, as shown by the arterial blood coming from it. Possibly a pint of hot salt-water was thus injected, and possibly between one and two quarts more subcutaneously—I think more nearly the latter amount. The reason I am in doubt is, that in her extreme and even violent restlessness she several times upset the vessel containing the solution.

The subsequent history of the case was thus reported to me by Dr. Mabbott: "Our patient hung along for six days on the ragged edge of dissolution, and then died of exhaustion. She had no fever, no further hemorrhage of great amount, though Dr. Burkelman was sent for late one night because of a certain amount of bleeding. Of course *any* flow was too much in her state. There was no involution of uterus appreciable at the end of six days; apparent absolute inaction."

Case III.—Marie M——, a servant, had been bleeding steadily from the uterus for six weeks, and had repeatedly refused medical aid, although her mistress was much alarmed by her pallid face. At length, on the night of September 16th, I was sent for in haste. Marie had fainted, and had with difficulty been restored to consciousness.

On examination digitally, I found a piece of flesh pro-

truding from a somewhat dilated cervix uteri. Touching it seemed to start bleeding afresh. She claimed virginity and was indignant when this was doubted. (*En passant*, next morning she admitted pregnancy, and said that a mass had "come away" some days before, and been disposed of in the water-closet.) She was put under ether; the uterus was emptied thoroughly by the finger and was washed out. It was only about three inches in depth; therefore I did not deem it essential to tampon its interior, but placed a solid and firm vaginal tamponade in place, which easily controlled bleeding.

The patient was alarmingly weak, as may be imagined from the duration of the hemorrhage as well as its amount. I proceeded to use arterial saline infusion. The femoral was entered at the first attempt, and a pint injected as hot as bearable. Following this, about two quarts were thrown under the skin here and there, four to six ounces in each spot, and all thoroughly massaged with vaselined hands.

The patient's pulse gradually gained in vigor. She was seen the following day by Dr. F. J. Brockway and myself, when the tamponade was removed. She complained somewhat of soreness wherever the needle had been inserted, but otherwise was comfortable. Her circulation had improved wonderfully. She made an uneventful and rapid recovery.

Perhaps this point will be as appropriate as another at which to refer to a criticism upon the new method of arterial infusion, which I have more than once heard; namely, that it is difficult to find the artery with the needle.

I can only reply that such has not been my own experience. A vessel big enough to contain a lead-pencil, and pulsating beneath the finger, ought to be an easy mark for a steadily and slowly introduced needle. Those who have not succeeded must in some respect have failed, either in delicate tactile sensation or else in technique. An example of the latter is a case published by Dr. Onuf-Onufrowicz, in the MEDICAL RECORD for October 1, 1892.

This gentleman very clearly and interestingly reports his case, but goes on to state that, upon endeavoring to introduce the needle into the artery by my technique, he pushed it into his rather fat subject at an angle of sixty degrees with the course of the vessel, directing it "with its point toward the foot." Naturally, he did not succeed in entering the femoral; although if his patient had been thin he might perhaps have done so.

I have now to record one remaining case in which saline infusion has recently been used, although only subcutaneously.

CASE IV.—On September 20th I was called to Elizabeth, N. J., by Dr. G. H. Bridgman. The patient was a baby of five months, suffering from gastro-intestinal catarrh, and had had so many watery movements, in spite of able treatment, that some hours before I arrived the case was regarded as hopeless.

I found a sunken fontanelle, pinched features, very rapid and feeble pulse; and felt that here, just as in cholera, there was indication enough for the Cantani method of treatment, so far at least as saline infusion subcutaneously was concerned. This was accordingly done: as usual, with very hot salt water, Davidson syringe, and hypodermatic needle. Into both thighs, just beneath the skin, a considerable amount was injected, which we estimated to be equal in proportionate bulk to two quarts in an adult. In addition I advised rubbing in hot cod-liver oil everywhere (except the abdomen) for an hour, three times in twenty four.

A considerable experience with infantile diarrhœa, begun ten years ago during a residence in the Nursery and Child's Hospital of this city, has convinced me that many a little life, otherwise inevitably lost because nourishment cannot be retained, may in this wise be saved.

In an hour of firm but gentle rubbing, nearly an ounce of the hot oil may be made to pass through the skin, and quite commonly the little patient falls asleep meanwhile, soothed by the massage. Sometimes hot, melted cacao butter will even more readily be absorbed than cod-liver oil. The next day Dr. Bridgman thought it wise to repeat the hot salt-water infusion, and so reported to me. The child steadily though slowly recovered from its gastro-enteritis. At this date, nearly two months after that of my visit, she is delicate, but has long been convalescent.

A few hours' investigation of this point, in the New York Academy of Medicine library, has convinced me that saline infusion in infantile diarrhœa is a treatment of extreme rarity. This should not be so. Between twenty five and thirty works on pædiatrics were consulted, and but two of these mentioned its use in this complaint. These were Henoch's "Lectures on Children's Diseases," vol. ii., p. 44 (1889), and *Revue des Maladies de l'Enfance*, p. 348, Juillet, 1892.

105 WEST SEVENTY-FOURTH STREET, NEW YORK.

NOTES ON ELECTRO-THERAPEUTICS IN PARIS.

BY HOWARD SMITH, M.D.,

LONDON, ENGLAND.

SINCE I came to Paris, I have visited the clinical hospitals and electro-therapeutic establishments, and have everywhere seen the appliances with which practitioners are already familiar.

There is one, however, deserving of special mention on account of several new features which are being experimented with: the laboratory of Drs. Gautier and Larat. They have made a practical therapeutic application of alternative currents through the medium of an aqueous bath, the electricity employed being obtained from the dynamos of an electric light company, modified and transformed by very ingenious contrivances.

The recent important experiments of d'Arsonval enable this treatment to be administered upon a sound physiological basis, he having proven that under the influence of these alternative currents the respiratory power of the blood is increased about fifty per cent. and hence nutrition must likewise be favorably influenced. We may indulge in the hope, based upon quite a number of successes, that chronic gout, rheumatism, and eczema, at least, may be much benefited by this means. They have also established a complete system of vibratory therapeutics.

Many of us have heard of the experiments of Drs. Vigoroux and Baudet with tuning-forks, made to vibrate by an electric attachment; the vibrations were conveyed to localized points of the body through the medium of a button placed in the desired position. Dr. Mortimer Grant, of England, later invented a vibrator or percutor, moved by clock work. Although good results were obtained, a later idea was to apply the vibrations to the nervous centres, and, to accomplish this, Drs. Gautier and Larat have had constructed an instrument closely resembling the form employed to take the shape of the head by hatters. When placed upon the head of the patient the many arms composing it are made to vibrate by a small electric motor on top. The effect is said to be wonderfully soothing to nervous patients and particularly beneficial in insomnia.

But what I most wish to draw the reader's attention to is a method called by Dr. Gautier interstitial electrolysis, which, although not altogether new, he has done so much for in the way of experiment and research that he may justly claim to have created it.

When an electrode of copper is connected with the positive pole of a battery and placed in the uterine cavity, for example, or embedded in the soft tissues, it is partially decomposed and an oxychloride of copper is formed, which permeates the tissues to a greater or less extent, depending upon the duration and intensity of the current.

In experiments upon the uterus of the rabbit removed from the body, he established the following facts:

1. The deposit upon the internal surface of the uterus is very appreciable.

2. The penetration of these salts of copper through the tissues is complete; the external surface is colored an apple-green as well marked as the interior.

3. One of the salts deposited is the insoluble oxychloride of copper; the other an organo metallic salt freely soluble.

A knife-blade placed in contact with any part penetrated by the salt becomes quickly covered with a deposit of metallic copper. By hypodermic injections in rabbits he found no toxic effects in quite large doses.

Let me add that the electrodes are of the purest material, being formed from copper deposited by galvanic action. High intensities are not required, and, as there is no cauterization, no scars result, which is of great advantage in some forms of disease, especially about the face.

The apparatus is of the simplest description, consisting of rods of various sizes for intra-uterine applications, needles and others of special form for the nasal cavities and for hemorrhoids, etc. They are easily cleaned with emery paper, and instead of insulating sheaths a solution of gum lac is applied. No binding screws are used, but fine wire wound several times around the end of the needle or rod of copper and attached to the battery in any convenient way.

In operating upon superficial tumors, sores, adenitis, etc., the author plants from two to twelve needles in the tissues, and after binding each connected with the other are attached to the positive pole of the battery.

He operates with low intensity from 30 to 50 milliampères, and the applications are of quite long duration, from ten to twenty minutes. In all cases it is best to reverse the current for a minute or more before withdrawing the needles which otherwise would be found adherent to the tissues.

Although the needles are scarcely discolored, if the punctures are examined with a magnifying glass it will be seen that the oxychloride of copper has stained the tissues far beyond the puncture, and that there is no trace of cauterization.

It is only a question, if pathological tissues infiltrated with this copper salt are restored to a healthy condition or not. The author of the treatment claims that it is undeniably more rapid and superior to any other in the treatment of uterine hemorrhages, endometritis and parametritis. Patients with interstitial hemorrhagic fibroid tumors, which no previous treatment relieved, even high intensities, have been cured of their pains, hemorrhages, and debility. Lupus of the face, hemorrhoids, and ozena are other diseases successfully treated.

The most interesting and important thing I have seen at the clinic of Dr. Apostoli is his demonstration of the practicability of ascertaining the condition of the ovaries as regards inflammation and suppuration by the application of the faradic and galvanic currents.

This subject was fully elaborated in a paper which he read before the Congress of Gynecologists at Brussels, September 15th, and will be published in the American journals; still a short *résumé* may be interesting: The application of the faradic current of high tension is a most efficacious remedy for ovarian pains of hysterical origin, while it is impotent to relieve these pains when due to inflammatory conditions of the appendages.

The application of these facts to diagnosis is evident. As regards the galvanic current, uterine intolerance is known to depend upon: *a*. Hysteria, in which case it soon passes off and may be readily recognized; *b*, fibrocystic tumors of the uterus of probably malignant origin; *c*, pelvic phlegmasias, including the intestines, which generally have a very characteristic history. If intolerance persists after the applications of from 30 to 50 milliampères, is followed by pain, fever, and no amelioration of the symptoms, and the above mentioned conditions are excluded, in all probability it is an ovaro-salpingitis, usually in a state of suppuration and demanding a surgical operation.

If, on the other hand, a dose of from 100 to 150 milliampères is well supported and followed by a diminution of pain, hemorrhage, etc., and without post-operative fever, the uterine periphery may confidently be stated to be in a healthy state, or at least there is no acute inflammatory lesion justifying operative procedures.

If the surgeon will avail himself of the advice of physicians skilled in this method of making a diagnosis, he will make fewer exploratory laparotomies and encounter fewer surprises when he does operate.

The last subject to which I would like to call the reader's attention, is the application of the alternative sensusoidal current to gynecology. The machine employed at the clinic of Dr. Apostoli is a magneto-electric machine of the Clark type, in which the ordinary stationary horseshoe magnets are replaced by circular ones which revolve around the bobbins. It is placed upon a sewing-machine table and made to revolve by the pedal going at the medium rate of speed, 4,000 to 6,000 alternations per minute, and a difference of potential of 32 volts at the maximum rate of speed, the alternations being from 11,000 to 12,000 per minute, and the difference of potential 64 volts. One pole is placed in the uterus and the other terminates in a large clay electrode upon the abdomen. The *séances* are of five minutes' duration, repeated two or three times weekly. During the last five months 34 patients with fibroids (12) and diseased appendages (22) have been treated, the total number of applications made being 320. Although not definitely established the following are the principal conclusions to be drawn from the experiments:

1. The alternative sensusoidal current applied intra-uterine is harmless and well-supported

2. Its application is not followed by a painful or febrile reaction, but is, on the contrary, most frequently accompanied by marked sedation.

3. It has no marked action in controlling hemorrhage, but, on the contrary, has sometimes provoked its continuation.

4. Upon pain its effect is very evident from the first *séances*, and frequently observable at their termination.

5. It is very advantageous in combating the leucorrhœa, which frequently, but not always, diminishes or disappears.

6 It has no appreciable action upon the hydrorrhœa found in connection with certain fibroids.

7. Its influence upon the anatomical regression of fibroids is not yet established.

8. It increases and favors the resolution of peri uterine exudates.

Further experiments may teach something more as regards the number of the alternations, voltage, duration of the *séances*, their number and frequency, which will give even better results, but for the present we may be contented to know that it is as Apostoli says, the remedy *par excellence* for pain.

An Unusual Number of Lumbrici.—Dr. F. C. W. Hounsell writes as follows in the *British Medical Journal:* "In August, 1891, I was sent for to see a little boy, whom I found in bed, very poorly, with temperature 104° F. History given: The patient has been ailing and out of sorts for some time; losing flesh, with constant hacking cough and, latterly, night perspiration. Physical examination revealed no disease of lungs, although breathing was rough. On inquiry, pain in abdomen existed, also mucus in the motions, but no blood; appetite capricious, with picking of nose and grinding of teeth; in short, all the usual symptoms of worms. Three powders of pulv. santonin—3 grains in each—were ordered alternate mornings, to be followed by castor-oil at night, with the result that ninety-seven ordinary round pink worms (lumbricoides) were evacuated. The child made a speedy recovery and was well in about ten days. The case is of interest from all the astonishingly large number of these ascarides which can exist in the bowels of a child of six years with no graver symptoms than those enumerated."

DISLOCATIONS OF THE SHOULDER.

By WILLIAM MEACHER, M.D.,

PORTAGE, WIS.

To the experienced surgeon this paper may seem to be uncalled for, or a repetition of what is to be found in all the text-books on surgery. But I have written it for the ordinary practitioner, who has occasionally to deal with dislocation of the shoulder, in the hope that it may be of service to some.

This is the most common of all dislocations, and one of the most fruitful sources of malpractice suits; and a large majority of these suits come from the failure of the doctor to diagnose the injury. The practitioner who recognizes a dislocation of the shoulder when called to the case, although he fails at reduction, is in little danger of being sued for malpractice, so I feel like attaching rather more importance, in this paper, to the subject of diagnosis than to that of treatment.

The books on surgery describe a number of varieties of dislocation of the shoulder, namely, downward, forward, backward, and downward and forward—subcoracoid, subclavicular, and subspinous backward on the scapula. But the fact is, as Gross says, that in almost every case the head of the humerus is downward and forward, and more or less under the coracoid process. It is rarely in any other position, and to have what the books call a subclavicular dislocation, there must have been sufficient force to drive the head of the humerus, after leaving the socket, through the flesh or under the pectoral muscles, toward the sternum, to an unusual extent.

A dislocation directly downward is seldom found, because, should the head of the bone leave the socket in a downward direction, it would slip forward, more or less, into the axillary space, where there would be the least resistance offered to it.

I fear that the young practitioner is often confused by finding so many varieties of dislocation of the shoulder described, and even if each of these varieties could be recognized, the treatment, with very few exceptions, would be the same in all.

Dislocation backward, called subspinous, is rare, but is quite as easily recognized as a dislocation downward and forward.

To examine a patient for dislocation of the shoulder, divest him of all clothing down to his waist, and do not allow any of the clothing to remain on the sound arm or lie on his lap, take it entirely away. Seat him on a stool of the same height as a common chair, but do not seat him on a chair if you can provide a stool for him to sit on; the back of the chair will be in your way. Direct the patient to sit upright, with his hands resting in his lap close to the abdomen. Now seat yourself on a chair, squarely in front of him. If he has a dislocation of the shoulder, you will observe:

First. That the two elbows do not hang alike; the elbow of the injured arm will be canted out from the body about as much as the thickness of the arm more than the sound one.

Second. The natural mobility of the shoulder-joint will be lost to a great extent.

Third. The edge of a yardstick, or similar straight object, held against the outside of the arm, will touch or rest on the outer condyle of the humerus and the acromion process. But if the shoulder is not dislocated, the prominence of the deltoid muscle will hold the straight-edge out, so that it will not touch the acromion process. The prominence of the acromion is generally very observable, and you can feel a marked difference from that of the sound side. If the patient is a fleshy woman, the difference may not show much, but can be plainly felt.

Fourth. Now examine the axilla, and if the head of the humerus is there, instead of in the socket, you can feel it hard and round.

Fifth. Next pass a tape measure around under the axilla, and up over the top of the shoulder, about an inch in from the point of the acromion process; and if a dislocation exists, you will find that this shoulder measures somewhere in the neighborhood of two inches more in circumference than the sound one.

This is one of the most important diagnostic means we possess.

Bryant says this was pointed out by the late Mr. T. Galloway, in his Jacksonian Prize Essay, in 1849.

Sixth. Lengthening or shortening of the arm may occur in dislocation, or the length may remain unchanged. If the head of the bone is below the socket, and not much inward, the arm will be lengthened. But the head of the bone may be so far inward, under the coracoid, that the distance from the point of the acromion to the outer condyle of the humerus may be the same as that of the sound arm, or the head of the bone may be far enough inward under the clavicle to shorten the arm.

Seventh. Ascertain if the patient can place the hand of the injured arm on the opposite shoulder, while the elbow touches the chest. It is said this cannot be done if the shoulder is dislocated; now, if the patient is a fleshy woman, with comparatively small bones, and unusually lax ligaments, and have a very full bust, I certainly would not place too much dependence on this test. In male patients, however, and women who are not very fleshy, it is pretty reliable. It is in these fleshy patients, especially in fleshy women, that a luxation may be very obscure. I would strongly advise everyone in all cases, if a satisfactory diagnosis cannot be made otherwise, to place the patient fully under chloroform. If after a thorough examination the diagnosis is still uncertain, another examination should be arranged for the next day, and on several succeeding days, if necessary. A dislocation that is ever so difficult to detect at first is pretty sure to become apparent before the time passes in which it can be reduced.

A dislocation backward — "subpinous" — requires a somewhat different description. Looking at the front of the shoulder, there will be seen the flattening of the deltoid and prominence of the acromion, as in the other forms of dislocation; but the arm or elbow, instead of being canted out from the side, will be close to it, and the arm will be held forward more or less. Looking at the back, the head of the bone resting on the scapula is generally plainly to be seen—a round, hard tumor.

Most of the text books on surgery direct the administration of an anæsthetic to reduce a dislocation of the shoulder; but many of them do not speak positively enough on this subject, and it is astonishing how often reduction is attempted without anæsthesia, and therefore often without success. I believe that one of the reasons why practitioners so frequently try to reduce shoulder dislocations without anæsthetizing the patient is because we still are governed to some extent by the teaching of the days before chloroform and ether. Another reason is that some dislike to put a patient under an anæsthetic; but there are very few cases in which reduction should be undertaken without having the patient fully anæsthetized.

Many practitioners labor under the impression that a dislocation of the shoulder cannot be reduced without a great deal of pulling, so not infrequently the combined strength of two or three men is brought into requisition to pull the unfortunate member, and often without any anæsthetic, all this expenditure of force resulting only in torturing the patient. To illustrate this point I will mention that, not many months since, a man came to me saying he had his shoulder dislocated two days ago. He said it had been "put back," but continued to pain him as badly as ever. Upon examination I found that a luxation still existed. When informed of this he became very much alarmed; he said the doctor who claimed to have reduced it got three men to pull the arm for him, and they pulled as hard as they could, the arm itself testifying to his statements by the numerous bruises on it, and patches denuded of skin. He was actually afraid

that his arm would be pulled off if another attempt was made to reduce it, because he supposed that in order to succeed in reducing the dislocation it would be necessary to pull the arm harder than it had been pulled before.

But upon being assured that if he would take chloroform very little, if any, pulling would be required, he readily consented, and the luxation was reduced by manipulation without difficulty.

To reduce a dislocation of the shoulder, place the patient on a firm, level bed, near the edge; put him fully under the influence of an anæsthetic. For this purpose I much prefer chloroform, because one gets more complete relaxation from it.

Reduction by manipulation should be tried first. It appears to be difficult for writers on this subject to make themselves fully understood when describing the movements of the arm and forearm which they recommend to be made in trying to reduce a dislocation. Professor Edmund Andrews, in his excellent treatise in the "International Encyclopædia of Surgery," on "Injury of the Joints," says: "By manipulation is meant a combination of the various passive movements, such as flexion and extension, adduction and abduction, circumduction and rotation, by which dislocations of the shoulder can be reduced without the employment of great traction."

I will attempt a little further description of reduction by manipulation.

The patient being fully under the influence of chloroform, and lying flat on his back on the bed, with the injured shoulder near the edge of the bed, place yourself at the bedside, a little above the patient's head, grasp the forearm at the wrist, flex the elbow until the forearm is at a right angle with the arm, holding the forearm perpendicular; grasp the arm at the elbow with your other hand, and while keeping the forearm perpendicular abduct the arm as much as you can without using much force. Now rotate it by pulling the forearm from the perpendicular over toward you, that is, in a direction away from the patient's feet; do not use much force in this movement either. Now carry the arm inward over the patient's face, and downward over the chest, at the same time turning the forearm downward toward the patient's feet, and straighten the elbow, thus bringing the arm down close to the patient's side; the last part of the manœuvre should be made rather quickly. If this does not succeed, after being tried two or three times, then have recourse to Cooper's method—the heel in the axilla. This is probably the most efficient operative procedure the practitioner can adopt. If the dislocation is on the patient's right side, remove the shoe from your right foot, if on his left side, from your left foot, seating yourself on the side of the bed, or on a chair close to it, or, if he lies on the floor (which is as good as lying on a bed, if not better, for this manipulation) seat yourself on the floor beside him, with your face toward his. Nearly all the works on surgery contain good cuts of this position. Now grasp the wrist of the dislocated arm with both hands, place the foot from which the shoe has been removed in the axilla, and with the arm at an angle of about forty-five degrees from the patient's body begin pulling steadily and quite strongly, making counter-extension with the foot in the axilla; after pulling steadily for a short time (if the bone does not come into place as it often will, by the pulling alone), swing yourself, together with the arm, toward the patient's body, until the arm is brought to the patient's side, continuing the steady pull as you move the arm inward. You will, by this inward movement, pry the head of the bone over your foot, out to the socket. This manœuvre may have to be repeated several times, but you are almost certain to succeed with it.

As Professor Andrews says, this procedure, although theoretically faulty, has probably been used in more cases than all other methods combined. It seems irrational, he continues, to pull the head of the bone downward when it is already below the socket. But the secret to success is the prying-out force which is exerted on the head of the bone.

A procedure which might be called a modification of Cooper's method may sometimes be advantageously employed; for example, in cases where the scapula, from injury or otherwise, is preternaturally movable, or where the head of the bone is driven very far inward under the clavicle.

Place the patient on the floor, on his back. When he is fully anæsthetized take off both your shoes, and seating yourself on the floor, at the injured shoulder, so that when your legs are straightened out they will be at right angles to the long axis of the patient's body; place one foot close up in the axilla, and place the inner edge of the ball of the other foot on the acromion process (you can in this way make very strong counter-extension on the acromion); then, taking a firm hold of the wrist of the dislocated member, with both hands, as in the last-described procedure, pull the arm steadily and strongly, keeping it at a right angle with the patient's body, rotating the arm more or less while pulling it.

A dislocation backward is to be reduced by one or the other of the two last-described procedures.

While there is very little danger that one man, in operating, if no mechanical appliance is used, and the patient is an adult, will pull hard enough to cause a rupture of the axillary artery or vein, still it is proper to exercise more or less caution in certain cases.

In operating, your hands or the patient's arm may become sweaty and slippery, so that you are unable to pull as hard as you need to; in that case a long towel, or a strong strip of sheeting, four or five inches wide, and of sufficient length, put on to the arm just above the elbow by a clove hitch, will give you the required hold. Old dislocations, ancient dislocations, and chronic and neglected dislocations, are terms applied to cases that have remained unreduced for several weeks or months. Generally, the older a dislocation is, the harder it is to reduce, and *vice versa*.

Generally, after five or six weeks the chances of reducing a dislocation of the shoulder become limited considerably; even after two or three weeks some dislocations will be reduced with great difficulty, while others may be reduced with no more trouble at the end of six or eight weeks. Cases are recorded of the reduction of shoulder dislocations after the lapse of all lengths of time up to a year, and even two years, but of course those cases were exceptional. Very seldom can there be any question about attempting the reduction of a dislocation that is not more than two or three weeks old; but when you come to one which is of six or more weeks' standing it always demands very careful consideration.

Continual pain and suffering from pressure by the head of the bone on the axillary nerves and vessels, with very little motion or usefulness of the member, would certainly warrant a good trial at reduction in cases that are eight or nine weeks old, more or less. On the other hand, if the patient suffer no pain, and have a fair amount of motion at the shoulder, except the overhead motion, as frequently comes to be the case in course of time, so that most of the usefulness of the arm is retained, then it is generally advisable to let the case alone, because of the danger to be encountered in trying to reduce old dislocations of the shoulder—the danger of injuring the axillary nerves, and, above all, of rupturing the axillary artery and vein. These accidents have occurred a good many times, and a number of patients have lost their lives in consequence. Before operating in old cases be sure to make the patient fully acquainted with the risk to be taken.

In operating in these old luxations it is best to employ the first two methods described—manipulation and Cooper's method, the heel in the axilla. The adhesions about the head of the bone are first to be broken up by manipulation, viz., rotating the arm quite strongly, first one way, then the other, then abducting and adducting,

then rotating again. A sufficient amount of force can be exerted on the arm by the leverage of the forearm to loosen the head of the humerus from its adhesions in most cases. When you think you have sufficiently broken up the adhesions, and loosened the head of the bone, then have recourse to Cooper's method, operating exactly as in a recent dislocation, only it may be necessary to use more force in the pulling and prying out. It may be necessary to repeat the loosening process several times before it becomes possible to dislodge the head of the bone and place it in the socket.

Progress of Medical Science.

Dermatol in Diarrhœa.—Dr. Colasanti (*Berlin. klin. Wochens.*, No. 34, 1892) has employed dermatol in the diarrhœa of typhoid, in enterocolitis, in the diarrhœa of malarial origin, as well as in that attending convalescence from acute febrile diseases, and is convinced that in this preparation we possess one of the best and safest locally acting agents in modern therapeutics.

Gonorrhœal Conjunctivitis. — In the *Geneeskundtijschrift von ned. Indie*, xxi., Haga reports good results from Burckharot's plan of treatment. Once every day a solution of salicylic acid is employed as a douche for the eye, 1 to 5 parts to 1,000. Every two hours one drop of nitrate of silver solution, 1 to 600, is carefully dropped into the eye. Compresses wet with tepid infusion of chamomile flowers (*Anthemis nobilis*), one quart containing fifteen grains each of salicylic and boracic acid, are used constantly.

When to Trephine.—Dr. Lanphear (*Kansas City Medical Index*) says we should operate in every case of fracture of the skull with depression, even if there be no symptoms whatever, and that instances of traumatic epilepsy will diminish in proportion to the frequency of operation, no matter how slight may be the depression. In all cases of local injury to the skull, followed by evidence of inflammation of bone or persistent symptoms of brain irritation, or of pus between the bone and dura mater, the trephine should be resorted to. Where after such injury unconsciousness persists for more than an hour, exploratory operation, including opening of the skull, should be done. The appearance of stupor some hours after a head injury indicates meningeal hemorrhage, and requires trephining at the point of injury if this be known, or at a point indicated by cerebral localization, usually the region of the middle meningeal.

Fracture of the Neck of the Femur Treated by the Thomas Hip-splint.—Dr. John Ridlon (*The Chicago Medical Recorder*, August, 1892) reports twelve cases of fracture of the neck of the femur treated by means of the Thomas hip-splint, which he thinks has many advantages over the methods now most in use by weight and pulley, long wooden side-splint, etc. The advantage of the plaster-of-Paris splint is chiefly theoretical, and counterbalanced by equally serious disadvantages. In women it is with difficulty kept free from wetting with urine, hidden points of irritation are complained of, and there is risk of pressure-sore, and the dressing cannot be changed without more or less serious harm to the fractured part. In the Thomas splint the author thinks we have an apparatus which presents the advantages that it secures posterior support to the fracture, gives fixation without compression of the fractured region, except posteriorly, allows the patient to be lifted with ease, does not interfere with the groin, favors cleanliness, admits fixative traction, can be applied without moving the patient and without assistance, and presents no difficulties after the initial application. When possible it is better to fit the splint before the patient has been moved from the spot where the accident has happened. The device aims to prevent motion in the axis of the limb; to prevent motion by bending the limb in any direction; to do this without circumferentially constricting the region of the fracture; and to enable the patient to have the bed-pan adjusted without pain, and without disturbing the relation of the parts. The following are held by Thomas to be the essentials of treatment: 1, To uninterruptedly and as effectually as possible arrest flexion at the hip-joint; 2, to continue the treatment until the symptoms of genuine repair and soundness of the joint are diagnosed; 3, to obtain the best possible restoration circumstances permit, so that no lameness attributable to flexion be a permanent reminder of treatment. The author agrees with Stimson that the principal aim of treatment should be to keep the inflammatory reaction within the narrowest limits and to secure union at the earliest possible moment, even if in a faulty position.

Chlorobrom in Sea-sickness.—Dr. Montague Gunning, writing in the *British Medical Journal*, says that he has relieved a number of cases of sea sickness by means of chlorobrom given in one to two tablespoonful doses.

Fracture of the Spine by Muscular Action.—At a meeting of the Paris Academy of Medicine, on September 27th, MM. Vernenil and Forestier reported the case of a man of good physique who slipped on the ice and saved himself from falling only by a violent effort. He immediately felt a violent pain in the lumbar region, which yielded after a few days' rest in bed, but a tenderness and slight pain on exertion persisted. Six months later he began to suffer from severe girdle pains, and soon thereafter a prominent knuckle was noticed in the lower dorsal spine. The original injury was diagnosed by the author of the paper as a fracture from muscular effort.

Bacteria of Phosphorescence.—According to a paper by T. Forster, of Amsterdam, the bacteria which produce the light of phosphorescence are able to multiply and develop at the freezing point of water. They not only live in the sea, but are met with in brackish and fresh water, upon victuals, manures, etc. This agrees with the fact that victuals kept for some days in an ice-chamber gradually assume a disagreeable smell and taste; and that meat can be preserved from putrefaction for days, but not for weeks. If foods are to be preserved at a low temperature for a long time, besides cold, a second element is necessary—dryness.—*Popular Science Monthly.*

Periodicity of Venereal Diseases.—Dr. Mounier, of Utrecht, is a disbeliever in the efficacy of the regulation of prostitution in diminishing venereal diseases. "The fluctuations of venereal diseases," he said, in concluding a report on the occurrence of these diseases in the Belgian army, "appear to follow constant general laws. These maladies increase and decrease without the least reference to the feeble efforts of the police sanitary regulations which are intended to put a stop to them."

Calomel for Hæmorrhoids.—The local application of calomel is recommended by Dr. James as a measure affording great relief in cases of irritable and inflamed hæmorrhoids. He says that he has never known it to fail.

A Substitute for the Nasal Douche.—Dr. Bloebaum no longer uses the nasal douche in removing crusts from the nasal cavity. He simply twists a long and thin roll of cotton onto a knitting-needle, introduces it into the nose, and withdraws the needle, leaving the cotton in the nose. A second and third are introduced thus, until the entire cavity is filled. Then one may begin with the opposite side and do likewise. In the course of a quarter of an hour the mucous membrane begins to secrete profusely, and if the cotton is then removed, it will be found that it is saturated with secretions, and the crusts lie on the rolls of cotton, thus leaving a nicely cleaned cavity for the application of the remedies. He never employs any watery solutions, but salves, which are rubbed into the nasal mucous membrane, or powders which are insufflated.—*Lancet-Clinic.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, November 12, 1892.

THE MODERN TREATMENT OF DIPHTHERIA.

A LITTLE research shows that during the past year over thirty different authors have contributed their views and results regarding the treatment of diphtheria. Of these one each was from Switzerland, Turkey, and Italy; two were Scandinavians; 3 Hungarians; 5 Americans; 60 French, and 12 Germans. The centre of interest in diphtheritic therapeutics seems to be, therefore, in Germany, while in England the subject apparently arouses little attention. A perusal of the various reports shows that a practically unanimous opinion exists as to what should be the object in treating diphtheria. It is to kill the bacilli and streptococci, to counteract the effect of their toxic products, and to sustain the strength of the patient.

Regarding the best way to do this, however, there is hardly any agreement. Leonardi advises a supporting and expectant treatment; he denies the value of ice and extols that of permanganate of potash and saline sprays. Dr. A. Baginsky reports the results of his experience in the Kaiser Frederic Krankenhause, where 244 cases were treated, with 40 04 per cent. of deaths. He thinks that the best disinfectant locally is corrosive sublimate, 1 to 3,000 for gargles, and 1 to 500 for local applications. He also approves of lactic acid and papagotin sprays for dissolving the membranes. While Baginsky may be right about his treatment, one must feel that it predicately does no good if forty per cent. of his patients die, even if his cases, as is stated, were bad ones.

Dr. Strübing uses locally solutions of codo-phenol, tincture of iron and sulphur, with lime-water gargles, and internally cyanide of mercury. Later he makes applications of carbolic acid, turpentine, and alcohol.

Dr. Wilhemy, of Berlin, has a mode of treatment which is heroic enough, and which, he asserts, has been uniformly successful when he saw the patients early in the disease. He wraps a bent probe with a thick layer of cotton, which is saturated in a twenty per cent. solution of chloride of zinc. This is applied to the throat, which is thereby thoroughly cauterized. Gargles of lime-water and oil of peppermint are then used, and in two or three days a milder cauterization is made. In advanced septic cases this treatment does no good.

Barbier, after many trials, finds that the most effective local application is a twenty per cent. solution of sulphocarbolic acid. This is made hourly during the day, less often at night. After the applications irrigation with a weak antiseptic fluid is employed.

Dr. Stein recommends most highly Burghardt's method of treating diphtheria. This consists of strong feeding, lime-water gargles, and the application locally of a powder composed of equal parts of flowers of sulphur and quinine.

Dr. Jänicke, of Görlitz, found by experiment that methyl violet had a most powerful destructive effect on the Loeffler bacillus. He therefore paints the throat with solutions of this drug every two to five hours. Dr. C. Höring has used the same treatment in fifteen cases, of which two died. He applies a three per cent. solution to the throat, previously dried. Dr. Taube, of Leipzig, has used methyl-violet in ten per cent. solutions, and Dr. H. Beyer employs a powder consisting of two parts of the methyl and ninety-eight parts of sugar.

Dr. E. Güntz thinks diphtheria can be controlled by making the patient drink a bottle of "chrome-water" daily, each bottle containing one-third grain of bichromate of potash.

Dr. Ozegowski for ten years has successfully treated diphtheria by pencilling the throat every two or three hours with carbolic acid, citric acid, and tincture of iodine, each three to five parts, brandy one hundred parts. Salt water gargles are also used.

Dr. André Martin used a local application consisting of carbolic acid and camphor, each one part, water and glycerine, each fifty parts.

Dr. Moskowitz, of Budapest, thinks it enough to keep the neck smeared with mercurial ointment; and Dr. Klein, of Lugos, takes the same view. Both authors lead one to conclude that the expectant treatment is as good a one as any.

Dr. Wissing believes in saturating the air of the room completely with oil of turpentine. He evaporates about five ounces daily in the room and near the patient.

Dr. Schwarz recommends rozo-iodol in solution or powder; and Dr. Hagedorn, of Hamburg, believes in the galvano-caustic treatment of the local process. Dr. R. Pimilla has used bromine successfully in two cases.

A review of the foregoing and of other communications leads one to somewhat gloomy conclusions regarding the therapy of diphtheria. Out of the mass of oils, astringents, antiseptics, dyes, solvents, and caustics, it does not seem possible to make any selections, to say that one is better than another, or that any of them do much good. With a definite problem now before him, it seems as if the physician treating diphtheria should be able to say what are the best drugs to apply, what is the best way to apply them, or whether any should be applied at all. We hope that in a year or two the therapeutics of diphtheria will be in a more satisfactory state.

The Venerable "Sanitarian" is much incensed over the Government quarantine order issued by the President. The *Sanitarian* thinks that the President's signature was secured to "the most disgraceful edict against practical sanitation that has emanated from any official entrusted with the duty of protecting public health during the last thirty years." The *Sanitarian* emphasizes this by putting on mourning borders.

FAILURE OF THE PLAN OF LICENSING PROSTITUTES.

Some interesting facts have been published concerning the regulation of prostitution in France. It seems that the attempted regulation of prostitution by licensing the keepers and inmates has had the effect of lessening the number of these houses very rapidly. In Marseilles, for example, the number has fallen from 125 in 1873 to 31 in 1889. The same thing has been noted at Lyon, Nantes, Montpellier, and Avignon. It is not to be inferred from this that the number of prostitutes is less, but quite the contrary. They object to being under state supervision and evade the law. But the conclusion is inevitable that licensing is an ineffective measure. And the opinion is gaining ground that the best thing to do is to educate the people and the prostitute to a knowledge of the dangers of venereal disease. The prostitute should be encouraged to go where she can get free treatment, and should be admitted to the hospitals, and then treated until she is well. It is also advised that if a prostitute, while suffering from a venereal disease be found still exercising her calling, she should be punished. The latter provision seems just, yet it might often happen that the woman was quite unaware of her illness, and how is her ignorance to be established? What shall be done also with the man who deliberately frequents brothels when he has an uncured gonorrhœa or syphilis?

On the other side of the question we append the following item which is credited to the *Union Médicale*: "2,941 registered prostitutes were arrested for various offences in Paris during the year 1891, and only 251 of them were found to be diseased; whereas, among 2,637 clandestine prostitutes arrested during the year for similar offences, 1,155 were found to be diseased."

HYPODERMOKLYSIS.

Hypodermoklysis is the name given to a somewhat novel therapeutical measure devised originally, we believe, by Professor Cantani, of Naples. The name is long and of formidable appearance, but as it is composed of three smoothly flowing trochees and pronounces itself easily, we can tolerate it until the thing itself is established in our art or dropped into oblivion. Dr. Hare has recently given a good definition of hypodermoklysis in an article reviewing some of the advances in therapeutics (*Therapeutic Gazette*). He states that hypodermoklysis is a method of supplying fluid to the body to replace that lost through excessive purging, as in cholera or in cases of hemorrhage. It is also used to wash out from the body various impurities circulating in the blood or other liquids, and to flush out the kidneys. The process consists in the introduction into the subcutaneous tissues of certain qualities of normal saline solution. As is well known, a quantity of liquid equal to four times that of the normal amount may be passed directly into the veins without producing a rise of blood-pressure, and experiment has shown that within fifteen minutes after the saline fluid flows into the subcutaneous tissues an increased flow from the kidneys takes place. It is not safe to infuse a greater quantity of liquid than one drachm to each pound of body weight (about one pint to an adult) in each fifteen minutes, as if this amount is exceeded, the accumulation of the liquid in the system is so great that the tissues become bathed and finally drowned, because the kidneys cannot excrete the liquid fast enough.

To carry out the operation the sterilized liquid to be infused—namely 7 parts of sodium chloride to 1,000 parts of water ($3\frac{1}{2}$ grains to the ounce)—is placed in a glass jar which is absolutely aseptic, and to which the air only gains access by means of a glass tube filled with sterilized cotton. From the lower part of the vessel leads a tube, to which is attached a trocar, also rendered absolutely sterile. The skin over the place where the liquid is to enter is to be rendered absolutely sterile, and the trocar is then inserted into the subcutaneous tissues of the thighs, or preferably of the abdomen, and liquid allowed to flow at the rate named, the pressure being obtained by raising the container two or three feet above the belly-wall. As the liquid enters, a swelling appears in the subcutaneous tissues, which soon disappears after the infusion ceases, and can be much aided in the absorption by the use of massage.

Cantani and Oser have used this method in cholera, but recent experience has sufficiently demonstrated that it has slight, if any, value. It does not compare in efficacy with intravenous saline injections. The results after hemorrhage, however, are said to be very good. Sahli, of Berne, has used hypodermoklysis with very good results in the treatment of uræmia, and he thinks that not only are the poisons washed out of the system by this method, but, in addition, that the dilution of the poisons prevents them from acting so forcibly. In septicæmia, diabetic coma, and similar states this method of treatment should be employed, and results carefully recorded and reported.

THE FOOT-BALL MANIA.

The foot-ball epidemic is upon us, and it may be noted that each year the attack is more widespread and violent. Throughout the East foot-ball has affected not only the colleges great and small, the preparatory schools and athletic clubs, but it has reached the young men of the small towns and villages, and foot ball is becoming as much the talk in the autumn as base-ball is in the earlier season. In England, every Saturday from September to April is devoted to foot-ball in all the towns throughout the land, and something of this sort is going to develop in the United States. The matter is one of importance to anxious parents, to growing youths, and to medical men. In England foot-ball casualties were very frequent, and formed a regular part of the medical chronicles of the week. Fatal accidents were not extremely rare.

Of late, we are told by Mr. Edwards in *The Nineteenth Century*, serious accidents are very uncommon, owing to the strictness of the rules and the enlarged powers of the referee. English foot ball has passed through its dangerous stage. In this country, the number of serious accidents is not great, but bruises, sprains, and fractures are very common. The ankle and knee are naturally the favorite joints to be affected, while the nasal bones are those which are the oftenest broken.

The increased interest in foot-ball has caused some natural, and perhaps justifiable, alarm, and we have been inclined to make dolorous comments. Athletic fevers cannot be checked, however, and the wisest thing to do

meanwhile is to urge those in authority to make the rules as rigid as possible and to give the referee full powers for punishing violent and unsportsmanlike conduct.

THE ETIOLOGICAL TREATMENT OF SKIN DISEASES.

It is becoming more and more apparent that successful treatment in dermatology must come to depend more largely upon etiology. The effect which the somewhat rapid transitions of views concerning the cause of many dermatoses has already brought about in the management of many conditions strengthens this belief. As one by one the various diseases of the cutaneous surface are found to depend upon some microbe, the treatment will naturally become more microbicidal; but the error will have to be carefully avoided of making the local treatment all-important and neglecting constitutional conditions which require attention not less than the external lesions.

Dr. Walter G. Smith has shown, in an excellent article published in the *Dublin Journal of Medical Science*, January 1, 1892, how recent advances in etiology have already had a decided bearing upon treatment. While Unna's "Flora Dermatologica" cannot be said to be counterbalanced by any array of new remedies, it is the presumption that each of the fifty mucors, and the twenty different kinds of penicillium, to say nothing of aspergilli and the various cocci and bacilli found in eczema alone, does not require a separate and special drug for its destruction.

The author referred to speaks especially of erysipelas, furunculosis, carbuncle, and whitlow as local diseases depending upon parasitic infective processes whose successful treatment requires the use of parasiticides. Thus in furuncle the indications are:

1. To destroy by parasiticides the intruding cocci before they have induced necrosis of tissue.

2. When necrosis has occurred, to hasten as much as possible the expulsion of the necrotic plugs with their contained cocci.

3. To guard against the development of new boils through infection by means of cocci spreading from the older boils.

4. To place the organism in such a position as to render it as resistant as possible to invasion by micrococci.

The parasitic nature of erysipelas is accepted as an undeniable fact, and the rejection of local astringents is amply justified as irrational, while the internal use of the much-vaunted chalybeates is considered useless.

Severe cases of pustular acne can be quickly and certainly cured only by following the same lines of treatment as are applicable to boils, *i.e.*, curetting or incising each lesion and carefully disinfecting its interior. Where this method is not available for boils, the old-fashioned poultice prepared with a 1 to 1,000 sublimate solution, or a four per cent. boric acid solution is useful. At night the boil may be dressed with a carbolic mercury plaster, or with equal parts of vaseline, zinc oxide, and four per cent. of boric acid. The writer has no faith in the reputed virtues of calcium sulphide in the prophylaxis or treatment of furunculosis, acne, and suppurating glands, and would place it side by side with what he terms that ludicrous specimen of therapeutic empiricism, viz., the treatment of amenorrhœa by pills of potassium permanganate.

HOW TO CURE ECZEMA.

We know that the information we are about to give will be eagerly accepted, because of the frequency with which the question is asked. Is was only the other day that a practitioner was overheard to inquire of a dermatologic friend, "What is the best thing to do for eczema?" Now, he might almost as well have asked, "What is the best treatment for disease of the skin?" since his question only excluded about two thirds of all cases. Eczema has an ever-present interest for the general practitioner, while it is to him that come the great majority of cases to be treated, and journals devoted to general medical topics are constantly disseminating knowledge for his guidance. In a recent issue of an exchange we find the following, which has already had a good start on its rounds, and will continue to be copied, we presume, until someone pauses to consider, as the editorial scissors are at work, that four drachms of salicylic acid to the ounce is rather strong treatment. Here is the prescription:

For Eczema with Abundant Desquamation.

(*Therapeutic Gazette.*)

℞. Salicylic acid..... gr. xv.
Oxide of zinc..... gr. xxx.
Vaseline..... gr. xxx.

Charity forces us to the conclusion that in the original an ounce of vaseline was written or intended.

Still in the same journal we find the following:

Pruriginous Eczema.

℞. Oxide of zinc, vaseline..... equal parts.

It may be well to incorporate with these, if pruritus is present, a little oil of peppermint or carbolic acid, in the proportion of 1 to 4.

This would make it appear that the zinc and vaseline in equal parts was intentional in the first prescription. But why call twenty-five per cent. carbolic acid "a little?" and in what forms of pruriginous eczema is pruritus likely to be absent?

The fact that there are so very many kinds of eczema, some depending on local, others on general, conditions; some sharply limited, while others extend over the entire surface; some simple, and others due to an association of etiological elements; renders any attempt to generalize as to the treatment of eczema a difficult, and usually a futile, task. Take, as an instance of a single regional division, eczema of the lips. Before we can enter upon a rule of treatment, we must further subdivide the subject into those forms which begin upon the skin proper, and those affecting primarily the vermilion border or mucous surface. Of the former we have the quite common eczema which appears beneath one or both of the nostrils, depends upon a discharge from them, simulates a sycosis, and is in all probability of parasitic nature. In such an instance the eczema is cured and recurrences prevented principally by treating the chronic coryza or other nasal trouble present. Another variety is that seen in infants, and attributed to a strumous diathesis. Here, certainly, remedies directed to the constitutional disorder form the appropriate treatment. Seborrhœal eczema of the lips,

whether beginning at the junction of the skin and mucous membrane, or affecting other parts primarily, constitutes a rebellious disease which may have to be combated with resorcine, sulphur, salicylic acid, citrine, or other ointment, for a long time, and may then not succumb without the aid of arsenic, cod-liver oil, or other internal agents.

Other forms of intensely itching dry and scaly labial eczema may be encountered, sometimes due to one cause and sometimes to another, and each particular case will have to be treated on its merits.

Marchand (*Thèse de Paris*) calls certain of these cases *Eczema de la Moustache*, which is not quite so bad as the term used by a well-known oculist of this city, who, in sending a patient to a skin specialist wrote: "I send you a case of moustachitis." Here again the question arises, shall the lip be shaved, or the hairs clipped short. Shaving will, as a rule, be found too painful, if there is much infiltration and inflammatory reaction, and, if carefully done with a sharp scissors, clipping will answer every purpose. Such hairs as are implicated in pustular formation can be epilated.

Besnier recommends complete epilation, followed by vapor douches, and continuous application of caoutchouc or rubber bound upon the lip, under which protection the irritation rapidly diminishes.

One of the most constantly praised applications in eczema of the upper lip is the Lassar paste, the composition of which is about as follows:

℞. Zinci oxidi,
Pulv. amyli..... .....āā gram. 10.
Vaseline..... gram. 20.
Acidi salicylici..... centig. 0.40

Dubreuilh omits the starch and adds about four grams of sulphur, from which combination he reports good results.

If the eczema is of the seborrhœal variety, attention must be paid to any existing pityriasis or seborrhœal eczema of the scalp; for, as Unna has shown, unless the disease located here be kept in abeyance, recurrences will continue to take place on other regions.

Enough has been said to show that there is no royal remedy, or even any general plan of treatment, for the cure of eczema, and as Besnier has well said: "He who will best treat eczema in general will be he who will analyze with the most solicitude and attention the conditions presented by each patient, and will know how to rectify his hygiene and correct whatever may be faulty in his organs or their functions.

When this lesson has been learned, a great deal will have been accomplished toward a knowledge of how to cure eczema.

THE INTERNAL TREATMENT OF PITYRIASIS VERSICOLOR.

It may seem strange to many that a disease whose etiology and therapy are so simple—a parasitic affection of the cutaneous covering, requiring only a few applications of iodine, sulphur, naphthol, or resorcin to remove all the lesions present—should require any internal treatment.

Such, however, appears not to be the case so far as two French physicians, De Molènes and Costilhes, are concerned. These gentlemen attempt to show, in an article published in the *Archives Générales de Médecine*, October, 1891, that unless internal treatment be combined with local applications the soil will remain the same, and internal disorders being left unchanged, the conditions predisposing to the implantation and development of the germ will often suffice to determine new attacks.

Among the disorders found associated with pityriasis versicolor, phthisis and dilatation of the stomach are most prominently mentioned.

It has been a common observation for many years that consumptives often acquire this disease, but this has usually been attributed to the fact of excessive sweating, keeping the skin soft, and in a condition favorable to germ growth.

Dilatation of the stomach has already been found in frequent association with a disease somewhat similar to that under discussion, to wit, pityriasis rosea.

In many non-parasitic skin diseases digestive disorders are well known to have the most important influence, and it seems not unreasonable to suppose with these gentlemen that parasitic ones may find more chance to spread where a defective elimination has reacted upon the emunctories of the skin. Here the surface becomes fatty and acid, two conditions favorable to the germination of parasites.

Before the Microsporon furfur was discovered, internal remedies were relied upon to effect a cure, while external applications held a very secondary position. This was because of the mistaken idea that the macula hepatica, as the lesion was then called, was due to liver derangement, or was dependent upon some stomach or blood disease.

The authors would not have us go back to a treatment based upon such erroneous views, but upon the fact that faulty digestion is a most fruitful source of the seborrhœal conditions so indispensable to the germs of pityriasis versicolor.

The cure of constipation and maintaining the whole digestive tract in as antiseptic a condition as possible are the chief aims of internal treatment as recommended.

After enumerating the many cathartics applicable to the various forms of constipation, the following formula is given, which has been found useful in the double *rôle* of antiseptic and laxative:

℞. Sodæ bicarb.,
Naphtol or salol.,
Magnes. calcin. ..... āā gram. 10.
To make thirty powders, one to be taken before each meal.

This, combined with such an external application as the following, recommended by Brocq, will be all sufficient to cure the attack and prevent recurrence:

℞. Acid. salicylic ..... gram. 2 to 3.
Sulphur precip..... gram. 10 to 15.
Lano"ini ..... gram. 70.
Vaseline ..... 18.

In this way the parasite is destroyed and the ground is rendered sterile.

A Boy Sentenced to Death in the Electric Chair.—A Brooklyn boy, only sixteen years old, has just been sentenced to death for murdering an infant.

News of the Week.

Dr. Charles Denison is a resident of Denver, Col., and not of New York, as stated in a previous article. We are sorry that he is not of New York after all.

A Correction.—Dr. E. B. Dench writes: "I beg to call your attention to an error which your reporter has made in the last issue of the MEDICAL RECORD (October 22d). In reporting, on p. 490, my remarks upon Dr. Knapp's paper, my name is given as F. E. D'Oench, and a similar mistake is made upon the same page under the remarks of Dr. Gruening at the end of the discussion. The error is not uncommonly made, but as the other gentleman might not care to be responsible for my remarks, I shall deem it a favor if you can correct the mistake."

Cholera and Quarantine.—At the last regular meeting of the Society of the Alumni of Bellevue Hospital, held at the Hotel Brunswick, Wednesday evening, November 2d, Dr. J. M. Byron read a paper on cholera in New York Harbor. It was discussed by Health Officer Jenkins, Drs. H. M. Biggs, and H. D. Chapin.

The Death of Dr. Frazer C. Fuller.—The following resolutions were adopted by the Medical Board of the City Hospital recently:

Whereas, It has pleased Almighty God to call our late associate, Dr. Frazer C. Fuller, from his field of labor in the City Hospital; and

Whereas, Dr. Fuller exemplified in his professional career the faithfulness and zeal that gave bright promise of future usefulness and distinction;

Resolved, That we, his associates in the City Hospital, express our sense of bereavement at his death.

Resolved, That we tender our sympathy to his family in their great affliction.

Resolved, That these resolutions be spread upon a special page of the minutes, and that a copy be sent to the family of the deceased, and to the medical journals of the city.

By the Committee.

T. H. ALLEN,
EDWARD S. PECK,
J. BLAKE WHITE.

Charity, Maternity, and Epileptic Hospitals, Blackwell's Island.—The Medical Board of the City Hospital has appointed Dr. D. H. McAlpin, of New York, curator, in the place of Dr. H. Biggs, resigned.

Digitalis and the Digitalins.—This much-studied subject has received some contributions from MM. Fouquet and Kiliani. M. Fouquet, in the *Bulletin Gén. de Thérap.*, publishes a study of the comparative value of the various commercial digitalins. He considers that crystallized digitalin, amorphous digitalin, and digitoxin, all possess the same degree of activity; and that these only ought to be employed in medicine, the crystallized digitalin receiving the preference. The best method of administration is as one large dose of one milligramme ($\frac{1}{66}$ of a grain) dissolved in a mixture of glycerine, rectified spirit, and distilled water. If necessary, half the dose may be given the next day, but it should then be discontinued on account of its cumulative action. M. Kiliani, in investigating a practically applicable method of preparing the really active principle of digitalis in a state of purity, has arrived at the following conclusions: 1. Besides digitoxin and the active substances, the different kinds of commercial digitalin hitherto known generally contain two perfectly amorphous glucosides. 2. The digitalin of Schmiedeberg is also a mixture; its action on the heart being probably due to the presence of a hitherto unseparated glucoside. 3. The digitalin of Schmiedeberg is, on the contrary, a distinctly individual substance, possessing in a marked degree the characteristic property of acting on the heart. The secondary cumulative effects of digitalis preparations is in all probability to be ascribed not to digitalin itself, but to those substances which are associated with it in the preparations of the drug which are generally used.—*The Pharm. Journ. and Trans.*, vol. li., p. 1061, 1892.

Changes in State Care of Lunatics.—The State Asylum for Insane Criminals at Auburn has been abandoned as an institution for lunatics, and its inmates transferred to the new asylum at Matteawan, near Fishkill-on-the-Hudson. By an official decision of Attorney-General Simon W. Rosendale, the Matteawan asylum has been entirely substituted for the old institution, which has ceased to exist legally, and commitments and transfers on "criminal orders" now apply to the new asylum. The Auburn institution was abandoned on account of insufficient capacity, and the State asylum at Matteawan has all the necessary qualifications for a modern hospital for the insane. It now contains nearly all of the "criminal insane" of the State. But the most important part of the recent changes on the part of the Commission in Lunacy is that referring to the separation of the criminal and non-criminal insane. The Matteawan institution has ample room for such a distinction, and the commission brings forward many sufficient reasons in its support.

The Treatment of Nocturnal Incontinence of Urine in Children.—Dr. Van Tienhoven (*Allg. Wiener Medical Zeitung*, 1890, No. 50) believes the exciting cause of nocturnal enuresis to be the incomplete closure of the prostatic urethra, during the general muscular relaxation of sleep. The urine collecting in the bladder soon finds its way into the urethral pouch, and gives rise, by its presence, to reflex detrusor spasm. To overcome this he advises elevation of the pelvis during sleep by means of a wooden frame, which raises the body to an angle of forty-five degrees. In this manner, he affirms, the urine is prevented from entering the posterior segment of the urethra.

A Home for the Dying.—There are homes for the aged, homes for the sick, homes for the blind and the deaf, homes for convalescents, and homes for the incurable, but the most unique and novel of all is a "Home for the Dying." This is the name of a London institution founded seven years ago by a Scotch lady. It has been so well patronized that it will be enlarged.

Intra-uterine Injection of Glycerine.—The injection of glycerine into the rectum has for some years been current in practice, and it is recognized in certain conditions to be a very convenient and efficient method of administering an enema. It strikes me as strange that a substance so efficient in emptying the rectum should until now have been put to comparatively few trials in empty-

ing the uterus of its contents, for *a priori* it seems a likely agent for this purpose. M. Pelzer records some observations made in the latter direction, and speaks favorably of intra-uterine injections of glycerine for the inducing of necessary premature labor as well as in cases of insufficient uterine contraction. His method of procedure is as follows: He takes a syringe of the capacity of one hundred and fifty grammes, or a little over four ounces, and, having filled it with pure glycerine, he attaches it, through the medium of a gutta-percha tube, to a perforated sound. Having cleared the apparatus of air in the usual way, he introduces it into the uterine cavity between the posterior wall and the membranes to the fundus of the organ. The glycerine is then injected and the pelvis elevated to prevent its too rapid escape. In a very brief space of time energetic contractions are set up. The effect of the glycerine is due in part to its mechanical action in separating the membranes from the uterine wall and in part to its chemical affinity for water, by virtue of which some of the amniotic liquid is abstracted, which in turn contributes to a further detaching of the membranes. On the whole M. Pelzer was pleased with his results and suggests glycerine as worthy a further trial in obstetric practice.—*Lancet.*

Sued for "Docking" a Horse.—At the suit of the Society for the Prevention of Cruelty to Animals, Dr. William M. Zuill, a professor in the Veterinary Department of the University of Pennsylvania, was fined by a magistrate $20 for "docking" the tail of a carriage-horse by request of the owner.

A Profession where there is More Room.—Frau Gelly enjoys the probably unique distinction of being the only person engaged in her occupation. Nearly every medical visitor to Vienna within the last ten years will remember her. She is employed as a nurse in Schnitzler's throat clinic in the general hospital and acts as an assistant instructor; but her forte lies in hiring herself out to medical men as a subject upon which to practise laryngology and rhinology. She comes to your rooms by appointment and brings all her own instruments. If you are a beginner, she explains the proper position for patient and physician, the adjustment of the forehead reflector, and the introduction of the throat mirror. Her throat is so insensitive that even the most awkward manipulations produce no gagging or other reflexes. She is able to tell whether the throat mirror is in correct position and to guide your hand so that you *must* see the vocal cords. She next points out with a probe the different structures to be seen. The next step is for the student to paint the larynx with some bland solution, and after that to touch the different parts with the probe as if applying a solid caustic. When you have become quite expert she introduces a glass bead so that it rests on one vocal cord and lets you remove it with Schrötter's forceps. The amount of confidence she has in your dexterity is indicated by the fact that she keeps a very tight hold of a thread attached to the bead. Passing on to the nose, you are given practice in making applications with a brush or probe to the different fossæ, in passing a catheter into the Eustachian tube, and in posterior rhinoscopy. It gave me a very queer sensation the first time I saw her introduce the Eustachian catheter herself. Frau Gelly has the reputation of being crafty. At the first lesson you cannot help seeing every portion of the larynx, but as you become more expert she makes it more and more difficult, until finally she is worse than the most refractory dispensary patient. Her object is apparently to show you the necessity for an indefinite continuance of the sittings. But it is just at this point that most men stop. Last year an American physician was working in Vienna on a modification (not yet published, I believe) of O'Dwyer's tubes, and during his experiments he intubated Frau Gelly's larynx a thousand times. She receives about eighty cents an hour, and is harder to make an appointment with than Professor Billroth. When she does make an appointment she never intends to keep it, but makes her appearance a week or two later. Why should not New York produce a Frau Gelly? There are students enough in the post-graduate medical schools to render the occupation profitable, if not agreeable.—Dr. S. Tousey in *New York Medical Journal.*

The Fresh Thyroid Gland as a Food.—A case of myxœdema, in London, is now under a curious treatment. The patient is a woman, aged forty, who for nearly three years has been under treatment for myxœdema. In every respect it is an extremely typical case; persistently subnormal temperature, general swelling of the integuments, dryness of skin, partial baldness, clumsiness of movement, slowness and thickness of speech, etc. The patient was admitted to the hospital in July, under the care of Dr. Hector Mackenzie, for the third time, in order to be treated by hypodermic injections of thyroid juice. In consequence of the difficulty experienced in obtaining the latter Dr. Mackenzie was induced to try the effect of feeding the patient on fresh thyroid glands. The result has been a very striking improvement. The myxœdematous swelling has entirely disappeared, the temperature has become steadily normal, the skin moist, and the speech natural. The patient asserts that she feels perfectly well.

The Parasitic Origin of Cancer.—In the August number of the *Annales de l'Institut Pasteur* M. J. Soudakewitch continues his account of his observations on intracellular parasitism in cancerous new growths. He strongly combats the idea brought forward by Professor Virchow that the parasites described by recent observers have little to do with the etiology of cancer. He still maintains that the structures he describes in the cancer-cells are true parasites; that by certain features they may be distinguished from various degenerated products and altered cells; he has now been able to see falciform bodies within these parasitic cysts. He has noted the division of the body into a larger number of smaller bodies, and he has found these smaller bodies increasing in size, ultimately forming groups of the larger organisms contained in a large mass of protoplasm. In the one hundred and ten cases he has now examined he has always obtained the same results. He thinks that the young parasite passes into the substance of the cell; that there it grows slowly; that the capsule that surrounds it becomes more and more marked; that the nucleus is gradually compressed until it takes the form of a flattened layer around the capsule, to which it is closely applied; the protoplasm of the cell is also gradually distended, becomes more homogeneous,

is not so brilliantly stained, and ultimately may form only a thin membrane around the parasite. The parasite is then set free, its contents become divided into what may be termed "spores," and these make their way into the neighboring cells, when the process recommences, so that a single cancer-cell may give rise to the contamination of a considerable number of those cells around it. He also holds, however, that the cell containing the cancer parasite may divide, and that the parasite may divide along with it, both of the resulting cells being thus infested. He does not, however, seem to take into account that these parasites as they grow must give off effete matter, which probably may have a most important influence in determining the proliferation of the epithelial cells in the immediate neighborhood, and that therefore it is not to be expected that one of these parasites would be found in every cancer-cell. These and other recent observations on cancer open up a new line of research, and one that promises to give us some new light on the etiology of this fell disease.

A Doctor Injured by the Trolley.—On October 26th, Dr. J. T. Whittaker, of Cincinnati, while driving beneath some overhead trolley wires, was struck by one of the wires falling into his carriage. Fortunately the doctor escaped with but slight injury, and in a short time was able to attend to his ordinary duties. This accident, along with others of the same kind, emphasizes the great danger of these overhead wires, and suggest proper means of precaution being taken. This is a feature of rapid transit that requires careful regulation.—*Cincinnati Lancet-Clinic.*

New York Physicians Have the Right of Way in accordance with the following city ordinance:

"SECTION 1.—Section 1 of Article I. of Chapter VIII. of the Revised Ordinances of 1880 is hereby amended by adding thereto at the end thereof the following words, to wit: Physicians having a police permit, as hereinafter provided for, shall also have a like right of way in the streets, and shall be allowed to cross processions as soon as possible, when answering calls for their services. The Superintendent of Police is hereby empowered to issue, upon application therefor, a proper permit to any duly registered physician, and this permit shall not be transferable."

Running Down the Quacks.—It is now about fifteen years since the Medical Society of the County of New York began a crusade against quacks. It went to work at first in a small way, with very little favorable legislation behind it and rather crude methods of carrying out its purpose, but little by little it has gained strength until it now has undertaken the task of keeping quack doctors out of the city. About two years after the County Medical Society began this sort of work the State Dental Association joined the hunt, and now both societies are in it hand-in-glove to rid the town of illegal practitioners. There is no scarcity of detectives. Most of them are women, and often they serve both societies. There is one, Miss Bertha S——, who has done well in both lines. Miss S—— is a pretty, innocent-looking German girl, but she knows almost enough medicine to be a doctor, and she has one molar with a large cavity. To the Medical Society she was invaluable. There were few diseases Bertha couldn't have. She knew the symptoms of almost all of them and described them glibly. Then the quack told Bertha what ailed her with more or less accuracy, and gave her some medicine, to be arrested next day on Bertha's complaint and fined from $50 to $200. In a dental way Miss S—— was very useful, and all on one tooth. She let one quack put cement in it; then she had him arrested. Then she went around the corner a day or so afterward and let quack number two change the cement for amalgam filling. This cost quack number two $50. Quack the third paid a similar sum for changing the amalgam filling for gold, and then an officer of the Dental Society unfilled Bertha's tooth and it was ready for business again. . . . Bertha almost cleaned out Brooklyn for the society, but at last she came to be known and some of the quacks refused to treat her.

Does a Moderate Use of Opium Shorten Human Life?—This was the question which a gentleman has just asked of several Life Assurance Companies for a satisfactory reply. The answer has come, as was naturally to be expected, decidedly in the negative. What do the "opium agitators" say to this? Are the Life Assurance Companies in a secret conspiracy with the Indian Government?—*Calcutta Medical Reporter.*

"Criminal Abortion among Some of our Respectable Married Ladies."—Under this title Dr. W. T. Kendall, of Meridian, Miss., makes some statements (*Mississippi Medical Monthly*) which show that a repugnance to maternity prevails in Mississippi as well as elsewhere. After citing a case in which a woman had injected two drachms of pennyroyal into the uterus without much effect, except to cause a colic, he gives some instances of the ways and means used in his locality to prevent childbearing: "A lady told me," he says, "she never intended to give birth to a child at full term. She said as soon as she was satisfied that conception had taken place, she would take two tablespoonfuls of oil of turpentine, and it would invariably produce abortion in her case, and that she had resorted to it on several occasions—would take one tablespoonful of oil of turpentine and repeat the dose in about three or four hours—the second dose always produced the desired effect. The third lady produced abortion by introducing a knitting-needle and puncturing the membrane. Another introduced a male catheter into the uterine cavity attached to a Davidson syringe and pumped a good deal of warm water into the uterus, which produced the desired effect. Some have learned the effect of tea made from gossypium root. I think our ladies of to day are surpassing the female slaves before the late war in the art of producing abortion. The negroes before the war would frequently object to bearing children and would resort to the use of cotton-root tea to produce abortion, which it invariably did. The first case I ever saw was a negro girl, eighteen years of age, who had taken a large quantity of cotton root tea to produce abortion, which she effectually did. When I arrived at her cabin I found her in the throes of the most violent convulsions I ever witnessed, and it was some time before I found out, through an old negress on the place, what caused the convulsions. I have known ladies to take large doses of double tansy, camphor, and many other remedies in astonishingly large doses."

Clinical Department.

SOME OBSERVATIONS OF CANCER OF THE BREAST.

By GEORGE F. SHRADY, M.D.,

NEW YORK.

THE question as to when a breast should be amputated for removal of malignant disease almost answers itself in the mind of every practical surgeon. The rule is, the sooner the better. But it is well known that we do not, save in a small minority of cases, see the disease sufficiently early to give us the best chances for success. The patient on first accidentally discovering a "lump" in her breast broods over her horror in secret and rarely consults her most intimate friends. She apparently shrinks from sharing her confidence, in the belief that even the members of her family will shun her as one having an incurable and loathsome disease. It is for these reasons that the surgeon does not see the disease in its incipiency and oftentimes not until it has passed the border-line of expediency as to operative interference. Whether to operate or not in a given case under such circumstances, with any reasonable hope of guarding against a recurrence, becomes to him a serious question.

Each operator is led by his individual experience to formulate his own rules. With his best judgment he is often inclined to expect too much, even though he is confident he can perform a thorough operation. There are always so many points to consider in reference to even a fair prognosis that he is inclined to give the individual the benefit of every doubt and virtually hope against hope. There is no rule to be laid down as to the rapidity of progress or as to time or possibility of recurrence in any particular patient. The safer way is never to promise anything further than that you will do your best to thoroughly eradicate the disease.

There are, however, general considerations which are hardly necessary to premise, which may aid us in the discussion of those cases in which we must draw the line when not to operate. Generally speaking, I am in favor of operating, even against apparent odds, so long as there is a chance of getting safely beyond the infiltrating area of the disease. While, save with the microscope, there is no way of positively determining the limit of infection we are oftentimes encouraged by ultimate success in the performance of most extensive operations with such an end in view.

It should be borne in mind in this connection that, although cancer is essensially an infiltrating disease, its focus of malignity is at its place of origin and but a comparatively slight distance around it, save when it invades the line of the lymphatics immediately connected with the original growth. The lymphatics being the direct lines of extension it does not by any means follow that all the surrounding tissues in their neighborhood and throughout their course are equally involved. This fact is often enough proven by noting the way in which recurrences take place. Exactly how much of the overlying and contiguous tissue shall be removed with the growth is a matter of judgment with the operator.

In estimating the chances of recurrence it is always well to bear in mind the very important part which the neighboring lymphatics bear to the cancerous mass. If a reasonably wide margin of skin and subcutaneous tissue is included in the extirpation it is safe to assume that the lymphatics are almost solely responsible for the subsequent spread of the trouble. This brings us to consider exactly what a radical operation means. In the first place, the entire gland—including, of course, the nipple and the usual elliptical enclosure of skin tissues—must always be removed. It has been shown over and over again, by the most careful microscopical examination, that when any part of the mamma is cancerous the remaining portions are sure to show some sign of degenerative cell-proliferation in varying degrees of progress. Not only is such a condition manifest in the cellular elements, but there are also unmistakable signs of reproductive activity in the periacinous connective tissue, which becomes infiltrated with small rounded cells.

It has been a question with many surgeons as to the practicability of always clearing the axilla as a necessary part of the radical operation. My own experience has led me to believe that it is always best in the first operation to be as sure as possible that all the glands in the axilla and neighborhood are removed. We should never be satisfied to complete an operation before, at least, examining the open axilla for enlarged and infected glands and giving the benefit of any possible doubt to the radical procedure. In fact, it is always best to make a thorough dissection, not only of the main axillary line of the lymphatics but its connections with the subscapular and subpectoral groups.

When such indications are properly fulfilled the operation becomes complicated with the dangers of wounding the axillary vessels and nerves and requires the utmost patience, care, and skill to carry it safely through. But there must be no compromise when once the thorough eradication of every suspicious kernel is determined upon. The failure to do this oftener explains a recurrence than anything else. Its demonstration is the subsequent enlargement of a neglected axillary gland imbedded in cicatricial tissue and in a situation more difficult than ever to reach in any secondary operation.

It is not the purpose in these comments to go into detail regarding the technique of the radical operation, as this is too well understood to need special reference. As a rule, I always clean out the axilla as a necessary part of every operation, and I have never had reason to regret so doing. Nor have I met with any accident that in the end compromised the life of the patient. With care neither nerves nor vessels need be wounded nor impaired usefulness of the arm result. Of course, when the pectoral muscles are cut away the motions of the limb become quite limited. Such a procedure, however, is in most cases unwarrantable, as there is not enough to be gained, considering the extension of the disease, to offset the chances of a speedy recurrence.

It goes without the saying that there must be no mistake in the diagnosis. That this is possible every surgeon knows. Several instances have occurred in my experience in which innocent tumors were christened malignant and in which the breast was condemned to amputation on account of simple growths, and also in consequence of deeply imbedded and firmly distended cysts. In one recent instance immediate amputation of the breast was advised by three very competent practitioners. The patient carried the tumor five years after that, at the end of which time I extirpated a large cyst and saved her breast. These cases are necessarily out of the category of recurrence. While it is fair to assume that every chronic tumor in the breast of a lady who is past forty years of age should be carefully scrutinized, we must not advise an operation too hastily. There are many varieties of breast tumors which are innocent in character and are sometimes difficult of diagnosis. Fortunately, there is always time enough in suspicious cases to study the character of the growth thoroughly before coming to a conclusion. In cases of reasonable doubt there is always a final chance of saving the breast by an exploratory operation.

While it is proper to take the most desperate chances with some hope, we have to consider another class in which the surgeon not only wisely hesitates but refuses to operate. In the experience at the New York Cancer Hospital, which in cases of cancer of the breast is exceptionally large, it is the rule not to operate when there is a continuous chain of lymphatic infiltration under the pectoralis minor and into the supraclavicular space. In times past I have attempted extirpation in several instances, and in one bisected the clavicle for the purpose, but invariably

there was a recurrence, either along the tracheal or cervical lymphatics.

Tumors which commence on the inner or sternal margin of the mamma are always in my experience less promising than those upon the outer portions. The anatomical explanation for this is in the arrangement of the lymphatics in that neighborhood and their connection with those of the mediastinal space. If there is any evidence of involvement in that direction, all operative interference is necessarily contraindicated. It is sometimes quite difficult to determine how much the axilla is infiltrated. The size of the tumor does not always demonstrate its absolute depth, but generally when the arm is œdematous the chances for operative relief are gone. Usually when the disease has gone thus far the supraclavicular glands are doomed, and the axillary vessels are hopelessly imbedded in diseased tissues.

There is a class of cases which is peculiarly obnoxious to operation and in which such a procedure should never be advised. This comprises the rapid infiltrating growths that appear to invade the entire breast, giving the organ an even, hardened enlargement with œdematous pitted surface resembling the rind of an orange. Although the disease appears to be sharply limited to the breast-tissues, the neighboring parts for a great distance around are always filled with active proliferating processes. Whenever operations are performed under such conditions the cases are sure to do badly, oftentimes the recurrence appearing before the necessarily large open wound is closed.

It is also unwise to interfere with the atrophic form of carcinoma as it occurs in elderly persons. While unmolested it is perfectly safe to leave it and take the exceptional chance of extension; an operation is almost sure to bring about a retaliation in the shape of a relighting of the disease with an attendant increase of malignancy. In this latter respect the results of operation are contrary to the rule when cases are judiciously selected. It is very properly held that recurrences after operations are generally less malignant than the original growths, and this is true even with repeated recurrences, provided the disease is restricted to a limited area.

It must often occur to the practitioner that there are at times different degrees of activity in cancerous growths which should be carefully considered in connection with the advisability of an operation. When active local infiltration is progressing it is best to wait until the parts become quiescent. The older writers speak of this as the inflammatory period, but modern pathology has given us a better explanation. In reality this condition means a new invasion of surrounding tissue, the involvement of new glands, and a new extension of infiltration.

The time has gone by for discussion as to the advisability of operations in properly selected cases. Statistics have proven that life is always prolonged, even when recurrence takes place. There is an average of a year of life in favor of operation, with a promise of less malignancy in recurrent attacks. But, best of all, some cases are absolutely cured, even after repeated operations.

8 East Sixty-sixth Street.

It Would be Instructive.—"There is one thing which patent-medicine vendors might do," says an exchange, "that would make even greater demands upon newspaper space, and that is to publish cuts of those who have tried their medicines, and died." Here is a valuable suggestion, that we would commend to the serious consideration of any new firm of cancer or catarrh "specialists" intent on driving older rivals from the field.

An Elderly Lady and a Large Baby.—Dr. E. E. Collins, in the *Nashville Journal of Medicine and Surgery*, reports the case of a woman, aged forty-three, whom he was called to attend in her thirteenth confinement. The labor ended in thirty hours; the baby, a girl, weighed 16½ pounds, the mother weighed 240 pounds, the father 289 pounds; total, 545½ pounds.

A SMALL ALLOWANCE OF WATER PER DIEM.

By THOMAS C. CRAIG, M.D.,

Passed Assistant Surgeon, U. S. N.

On August 26, 1892, the American ship William A. Campbell, was wrecked by a cyclone about twenty-three hundred miles southeast of Hilo, Hawaiian Islands. The same day the captain and crew abandoned the ship in two small boats; the larger boat being in charge of the captain and having eleven men, while the smaller one, an eighteen-foot boat, was in charge of the first mate, with ten men. They had provisions and water for twenty days, it being, of course, the intention to put each one on the smallest quantity that would possibly sustain life. Only one boat—that in charge of the mate—reached shore; and when it is remembered that an eighteen-foot boat, with eleven men, sailed the open sea for a distance of twenty-three hundred miles, it becomes perfectly marvellous to know how they managed to keep alive. There was no rain during the twenty-four days, consequently their only supply of fresh water was what they took with them from the ship.

The day they left the ship, the mate calculated that it would take twenty days to reach Hilo, and that only half a condensed milk-can of water (about six ounces) per diem could be allowed per man. Of hard-tack, canned meats and fruit they had enough for twenty-five or thirty days. For the first five or six days they were quite comfortable; in addition to the hard tack and water a two-pound can of fruit was daily equally divided among all, but at the end of that time, the fruit being all used, nothing was left except the water, hard tack, and the canned meat, and the latter was so salty that it was eaten with great difficulty. The constant crave during the whole time was for water. Some of the more reckless ones would drink their whole allowance at once, while the more thoughtful ones would merely moisten the lips and tongue, swallowing perhaps a teaspoonful; they would thus extend their allowance nearly the whole day. These were the ones who withstood the suffering best.

The most distressing symptoms were first a dryness of the mouth, with secretion of thick, tenacious saliva; then followed dryness of the fauces and pharynx, inability to swallow, and pain of an acute character in the throat; this pain would become so intense as almost to be unbearable. At the end of the sixteenth day the canned meat was all consumed, and nothing was left except the hard-tack and water.

At the end of the nineteenth day the water was all used and nothing remained except hard-tack. It was then found that they could not eat the hard tack, because it was so dry that it could not be swallowed. Dipping it in the sea-water and then eating it was tried, but it was discovered that the sea-water only tended to aggravate their thirst. Thus it was that for the last five days they had no water to drink, and were unable to eat the hard-tack they had. They gave up hope of reaching land, their strength failed them, they emaciated and became desperate and reckless. They had not room enough to lie down, and what little sleep they had was troubled with dreams of cold flowing springs, ice-cream, iced water, and all kinds of cold drinks. Although they were within the tropics, under a hot broiling sun, they perspired very little. Notwithstanding the small amount of water taken the amount of urine voided was about the normal quantity; this statement being told me by the mate. The bowels were extremely constipated in some, the worst case having but two passages in twenty-four days.

Scurvy attacked most of them; their gums swelled and became very tender, their feet, legs, and hands were more or less swollen; a purpuric eruption appeared, covering nearly the whole body, while in many places the skin ulcerated deeply. Their thirst became so intense that they began drinking their urine. One, not being able to pass enough urine to satisfy his craving, begged and obtained

an additional quantity from one of his friends. Toward the last part of their journey nearly all of them had become so exhausted that they were perfectly indifferent as to whether they reached land or not. They were rescued by some fishermen near Hilo. The fishermen knew enough to give them only a small quantity of water and fruit at a time during the first day. In several days, under good nutritious food, they recovered their strength, and are now being treated for their scorbutic condition.

Had even the small allowance of water lasted until the end of their journey they feel confident that they would have reached land in good health Bathing the head, body, and extremities with sea-water was tried, in the hope that enough would be absorbed to allay thirst in a measure, but it was found to do no good and was discontinued.

I have written the foregoing meagre report merely to call attention to the small quantity of water that is absolutely necessary to sustain life in a crisis.

October 3, 1892

CHEWING-GUM IN FEVERS.

Dr. R. I. Bond, of Hartshorne, I. T., writes: "The salivary glands play quite an important part in continued fevers, yet they are not considered in the treatment of the case. One of the first and most important restrictions in the patient's dietary is to drop all solid food from the list at the physician's first request, and just then the salivary glands begin to lapse into a torpid condition which very often results in an inflammation and, finally, suppuration, and that disagreeable dryness to the tongue and fauces so uncomfortable to the patient. For the relief of this trouble I have found nothing of so much importance as some nice form of aromatic chewing-gum, which relieves the thirst and dry mouth, improves the appetite and digestion, and restrains nausea, if any. Hence some of the most disagreeable accompaniments of the disease are mitigated. I believe also that it materially aids the absorption of the medicine when the alimentary tract is so impaired by the incessant fever.

"I do not claim originality in this treatment, although I have never found any reference to anything of the kind. However, it may have been regarded as too simple to need mention; still it is, in my estimation, quite important in any continued fever."

THE ESSENTIALS OF A GOOD STETHOSCOPE.

By C. B. LONGENECKER, M.D.,

PHILADELPHIA, PA.

A stethoscope may be regarded either as an instrument of convenience, or else an instrument which has for its prime object the conduction of sound to aid the hearing. If the former, errors of omission or commission by the maker may be pardoned. But, if the latter, anything that retards or prevents conduction of sound is a detriment, and insomuch as the maker fails to avail himself of good principles of construction just to that extent does the stethoscope fail to be the most efficient instrument for which it is intended.

In the Medical Record for October 22d Dr. Charles Denison has an article under the above heading, and many of his points are well taken, especially the one in regard to large calibre of tubes for the conveyance of sound.

I possess a Cammann binaural stethoscope, made by one of the best makers in New York, and supposed to be up to date in construction. After reading Dr. Denison's article I examined it to see if any of the faults he described were present. It did not take a very extended search to find some of them. One chief fault was the small calibre of the holes in the rubber parts and brass tubes. Another was that the woven covering of the flexible tubes had frayed out before being put together, and this partly occluded the openings.

The test that Dr. Denison describes was used in determining efficiency, viz.: placing the watch on the table, covering it with one hand, and applying the stethoscope to the back of the hand. The result was not very good. I then enlarged the holes in the rubber parts as large as could be without weakening them. This was considerable. I also removed the fringes, and rounded over some corners in the brass work. Of course it was not possible to enlarge the brass tubes.

After cleaning and putting together, the test was again applied. It was astonishing to note the difference, and the intensity of the sound was increased by fully one-half, if not more. It is hardly necessary to add that this result was extremely gratifying, as it increases the efficiency and range of the instrument by just that amount, which is not a trivial thing.

This plainly demonstrates that the calibre of tubes, smoothness, freedom from projecting angles, etc., have much to do in conveyance of sound in the stethoscope. If the makers would take heed to this simple point it would result in a more efficient instrument, to the great benefit of all who use this convenient aid to diagnosis.

Meanwhile, let the possessors of stethoscopes take them to a mechanic and have their internals curetted, and some of the strictures enlarged, and they will find themselves possessing a decidedly more efficient instrument.

3501 Hamilton Street.

SCORBUTUS IN INFANCY.

By JAMES McMANUS, M.D.,

ASSOCIATE ATTENDING PHYSICIAN NORWEGIAN HOSPITAL, BROOKLYN, N. Y.

I was called in September, 1890, to a child, W. M——, aged twenty months, bottle-fed, who had been having a diarrhœa for some weeks. The child had only a few teeth, and there were besides other marked evidences of rickets. The diarrhœic stools were of a dark grumous character, there were ecchymotic spots over the lower extremities, and on the right leg, midway between the knee and ankle, there was apparently a bruise, which was tender; the mother denied that the child had received a bruise. The gums were swollen and bled readily on slight pressure. The child had been fed upon condensed milk alone, which it devoured ravenously and occasionally vomited. I gave it calomel, bismuth, and lacto-peptine; ordered fresh cow's milk, beef-tea, orange-juice, and lemonade, and at my third visit, one week later, all the scorbutic symptoms had disappeared. After that it was put upon appropriate treatment for rickets, which now, happily, it has recovered from. I am impelled to write this from reading the interesting case reported recently in the Medical Record by Dr. Walter Lester Carr.

VITILIGO IN A NEGRO.

Dr. D. A. Richardson, of Shelton, Conn, writes: "In the Medical Record for September 24th, Dr. A. B. Holder says of vitiligo: 'The two most extensive cases I have seen in any race are on this [Crow] reservation.' If Dr. Holder will communicate with his neighbor, H. C. Dunavant, M.D., of Osceola, Ark., he will receive evidence to corroborate the following:

"Henry W——, a negro, about fifty or sixty years of age, died during 1885 or 1886 from retention of urine. He was at the time of his death white, with the exception of a ring of brown a quarter inch in diameter about the urethral orifice, and a few spots ranging from the size of a pin-head to a maximum of two inches. The hair was wavy. His children, who were black and born of a black mother, told me that he had been within their memory as black as themselves and his hair as curly as theirs. I think this case must have been as extensive as that of Hits on the Hip."

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, October 27, 1892.

ROBERT A. MURRAY, M.D., CHAIRMAN.

Adhesion of Nymphæ after Labor.—DR. BROOKS H. WELLS related a case of a woman who, some time after having given birth to a child, complained of certain symptoms which led to vaginal examination, when he found the edges of the labia minora or nymphæ grown together. They were divided by the knife under the influence of cocaine. There was also some erosion of the cervix. Before childbirth coitus had been satisfactory. Afterward, entrance was effected only after repeated trials, and the husband, thinking the wife cared nothing for him, sought a divorce.

Sarcoma of the Uterus.—DR. C. D. JONES presented a uterus, the seat of sarcoma. The organ was enlarged to the size of a pear; the appendages were also pathological and were removed. He also presented the same organs from another patient, the seat of malignant disease.

Case of Instruments for Transfusion.—DR. H. J. GARRIGUES presented his case of instruments for transfusion, either of blood or saline solutions. He also presented a symphyseotomy knife, and the Chairman said this form of knife had been used in the first case of symphyseotomy operated upon in this country. It occurred in New York a short time ago. Since then the operation had likewise been done successfully in two cases in Philadelphia.

Induction of Labor by the Introduction of Glycerine.—DR. J. CLIFTON EDGAR presented a syringe with tube connection for the introduction of sterilized glycerine into the uterus in cases of pelvic deformity or other conditions demanding the induction of premature labor. The advantage of this method over the catheter was that it acted more quickly. He had had occasion to use it in one case only, and in that one the pains began within two hours. The method was now being much used in Europe.

Reprehensible, Unnecessary, and Necessary Antiseptic Midwifery.—DR. H. J. GARRIGUES read a paper with this title. In the way of reprehensible midwifery he alluded to the custom in an institution in St. Petersburg, thirty years ago, of washing out the uterus in every case with a solution of chloride of lime. Recently a Frenchman writes that he uses a solution of 1 to 2,000 of corrosive sublimate for washing out the vagina twice daily some weeks before delivery. In the last week, however, he introduces an iodoform tampon. It was unnecessary to say that this custom was reprehensible. Whenever corrosive sublimate was used at all it should not be stronger than 1 to 5,000.

By way of illustrating antiseptic midwifery he contrasted the results of the practice in the New York Maternity Hospital and in other similar institutions, of recent years, with those obtained before such antiseptic methods were introduced. In the New York Maternity, during the nine years, 1875 to 1883, out of 3,504 women confined 146 died. During the first year after the adoption of the new method, in 1883, out of 102 deliveries there was no death. Since 1883 there had been 3,170 confinements with a mortality of only thirty. Could they change the conditions existing in the Maternity as they would desire even this low mortality might be reduced, as it had been in some continental institutions and in the Sloan Maternity, where more or less similar antiseptic methods were employed. About the only change in antiseptics which they had made at the New York Maternity from what they had employed for a number of years was to substitute creolin for corrosive sublimate in vaginal and intra-uterine injections. He now used one per cent. solution creolin instead of two, as the latter strength was irritating to some patients. Creolin possessed the very valuable qualities of being lubricant, antiseptic, and hæmostatic, besides being so innoxious that it could be taken internally in large doses without causing disturbance.

It was a question whether some of their minor practices might not be dispensed with. For instance, when he was last on duty at the Maternity he did not give ergot, and saw no disadvantage from it.

The question whether it was advisable to give a vaginal injection or injections before labor, was still being agitated, some authorities advocating the practice and others disapproving of it.

Dr. Garrigues thought it well to give a single injection, but that repetition of it might lead to harm by softening and carrying away the epithelium. He was opposed to rubbing and scraping the vagina.

After birth of the child no uterine injections should be made unless it had been necessary to introduce the hand. An antiseptic bandage should be applied over the vulva after delivery. Its deodorizing quality insured sweet air in a ward even where there were many women.

Some obstetricians at present went so far as not to permit even of a vaginal examination in apparently normal cases. The author thought this was going to extremes, and prevented knowledge of the condition of the parts and the progress of the case which the attendant should have. With antiseptic precautions it should not endanger sepsis. The nurse, however, should not make vaginal examinations. Any instruments used should be boiled and rendered strictly aseptic.

Failure to carry out these antiseptic practices by physicians generally had led to a reversal of the old rule, and made it safer to the mother to be delivered in an institution than at home with the family physician attending. He therefore closed his paper with the motion, which was later adopted, that in the opinion of the Section it was the duty of every physician to surround his cases with the same safeguards as were being used in hospitals.

The paper was discussed by Drs. Grandin, Malcolm McLean, Collyer, Vineberg, Agramonte, the Chairman, and the author. There was no difference of opinions in the essentials of cleanliness.

Movable Kidney.—DR. GEORGE M. EDEBOHLS read the second paper on this subject. In view of the fact that movable kidneys had been treated for more or less the past dozen years by different authors, it was astonishing how little was known about it by most gynecologists. The condition was, in the majority of instances, one of the easiest to diagnosticate. But when it came to treatment he had found little satisfaction until he began, in the severer cases, such as called for radical treatment, to perform nephrorrhaphy in a manner which he described later; movable kidney existed in about one of every six gynæcological cases, but not all producing symptoms. One must determine in a given case what of the symptoms were caused by the movable kidney, and what by other abnormal conditions, especially of the genitalia. As to causes, some had laid stress on tight lacing, but the author had found a snugly fitting corset give most relief. The chief cause, in his opinion, was absorption of the supra-renal fat. The condition might develop suddenly, but doubtless usually required months or years. The path of dislocation varied, and might be in any direction after the arc reached ten or twelve centimetres. It seemed much more common in women than in men, he having seen it in but two men. The suffering in the early stages was apt to be worst. There was a difference of opinion as to the mode of causation of the digestive and other symptoms, the author's own view being that they were caused by traction upon and irritation of the solar plexus of nerves—the sympathetic abdominal centre. As to prognosis, when the kidney once became movable it never again became firmly fixed, although the mobility might be lessened by deposit of fat.

Dr. Edebohls had performed nephrorrhaphy eleven

times, with one death. Death was due in the one case presumably to diphtheritic peritonitis from germs in his own throat, as afterward a cold which he had, slight at the time of the operation, was said to be diphtheritic. He had seen hæmaturia or albuminuria after the operation in only one case.

Nephrorrhaphy alone, or supplemented by operations upon the genital tract, had cured his patients of their symptoms. In one the left kidney afterward became also dislocated and caused a return of the symptoms, but when the patient took on more fat she became more comfortable.

Dr. W. Gill Wylie thought movable kidney due largely to imperfect development and enervating modes of life, and was apt to be accompanied by relaxation of attachments and displacement of other abdominal and pelvic organs. Tight lacing was a cause, although later the patient might feel some relief from a firm corset.

Dr. Boldt had not found movable kidney so frequently, and thought the author had drawn a more definite picture of the symptoms to be ascribed to the displacement than clinical facts would perhaps justify. That traumatism could produce the condition was proven by one of his cases.

Dr. Robert T. Morris said movable kidney was much more common in women than in men. Tight lacing in girls pressed the liver, etc., downward, and tended to cause displacement of the kidney; yet, short of an operation, nothing gave as much relief as a snugly fitting corset applied while on the back.

Dr. Collyer thought displacement of the abdominal viscera much more common than was generally supposed, and due largely to lack of assimilation.

New Instruments.

SOME PRACTICAL USES OF THE OPHTHALMOMETER OF JAVAL-SCHIOTZ.[1]

By F. B. EATON, M.D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY, MEDICAL DEPARTMENT, OREGON STATE UNIVERSITY, PORTLAND, ORE.

What are the practical advantages of this instrument? Like all other apparatus of novel use, it was at first misunderstood, and condemned by those who had not the skill or patience to make it useful; yet it is not at all difficult to manipulate. I remember that, on my return from Europe three years ago, I asked the chief of clinic of a well-known New York oculist what he thought of it. He said the clinic had possessed one for some time, but that it was of no practical use, and had been put away. Yet it had been employed daily by Dr. Swan Burnett, of Washington, with great success for a considerable period, and he had carefully explained the manner of manipulating it. Now, few oculists who can afford it, would willingly be without it. Landolt,[2] referring to this instrument says: "These instruments may render service when the dioptric system of the eye is reduced to the cornea alone, in aphakia. But in an immense majority of cases the determination of the curvature of the cornea is far from sufficient to acquaint us with the amount of astigmatism." Later clinical experience of many observers proves that the above statement is incorrect, for, on the contrary, it is known now that in the great majority of cases, all but one-half of one diopter of the astigmatism is caused by unequal corneal curvature.

The use of this apparatus is well nigh indispensable in determining the astigmatism of the very young, the illiterate, the dull, and the amblyopic patient. On a number of occasions I have quickly and correctly measured the astigmatism of so high a grade that the ordinary tests by test-type, radiating lines, etc., had failed in the hands of others to detect the condition, or the eye had been pronounced incurably amblyopic; while the ophthalmometer had enabled me quickly to pick out the strong cylinder which gave normal or nearly normal vision.

One of the uses of the instrument is to detect spurious astigmatism, caused by unequal contraction of the ciliary muscle, which renders the lens more convex in one meridian than another. We can prove this by putting weak cylindrical lenses before a normal eye, which will often, by its ciliary muscle, correct the artificial astigmatism so produced. But the great proof was afforded by the experiments of Dobrolsky, who completely paralyzed the ciliary muscle of certain eyes by the prolonged use of atropia, when regular astigmatism was found, although there was no sign of it before. The atropia could not affect the cornea, and the astigmatism which really existed was neutralized and corrected by unequal contraction of the muscle. I will cite a case of my own which illustrates this fact conclusively:

R——, aged sixteen, consulted me January 20, 1892. Eyelids sore at the edges as a young child. Reads a good deal. I found severe ulcerative marginal blepharitis of all four lids. I used oil of cade, yellow oxide of mercury, and silver nitrate; the eyes improved, but persistently relapsed. I suspected some refractive error and strain, but patient asserted positively that he could read any length of time without any discomfort. Moreover, on testing the acuity of vision I found it was $\frac{18}{20}$ in each eye, and he refused cylinders, which made vision worse. The Javal ophthalmometer gave, however, in the right eye 2.00 dioptries of astigmatism, and in the left 1.50 dioptry. The astigmatism must therefore have been disguised by spasm of the ciliary muscle, a fact which I proved by using atropia for two weeks, when the refraction was found to be R. with + 1.50 cyl. axis, 110°, vision = $\frac{18}{20}$ L. with + 0.25 spherical, combined with + 1.00 cyl. axis, 70°, vision = $\frac{18}{20}$. The eyes now rapidly recovered on my prescribing the above cylinders, and remained well.

Another recent case illustrates the value of the instrument in avoiding error: M. B——, aged twelve, saw me November 14, 1891. Her mother stated that at school the girl could not see the black-board, and complained that the eyes became very tired when she read.

By the shadow test (retinoscopy), I found in the right eye: myopia — 3.50 D, and astigmatism against the rule (highest horizontal); and in the left, myopia — 4.00 D. Testing with test-type I found myopia and great spasm of accommodation. The ophthalmometer gave R. lowest meridian at 10°, highest at 100°, and the astigmatism was 1.00 D. In the L. lowest, 180°; highest 90°; amount 0.75 D. Owing to the spasm of accommodation, I used atropia for three days, when the refraction was found to be approximately R. with — 3.00s. spherical glass, V. = $\frac{18}{20}$ L. with — 3.00 spherical V. = $\frac{18}{20}$. R. would take no cylinder unless the axis was held vertically. After several weeks of rest without atropia, V. R. with — 3.50s. ⌒ — 0.50 cylinder axis, 100, V. = $\frac{18}{20}$. After testing this eye with test-type and lenses a while, spasm appeared, and there was no astigmatism to be found by the fan of lines, all the lines looking alike. The astigmatism was, in other words, corrected by uneven contraction of the ciliary muscle. The eyes were rested strictly for two days, when retinoscopy gave R. astigmatism of 0.50 D., the highest meridian being vertical, thus corroborating the result found with the ophthalmometer. As long as the spasm lasted the right eye took the concave cylinder with its axis vertical, but when the ciliary muscle ceased to over-correct the astigmatism, owing to the paralyzing effect of the atropia, the cylinder cleared up the sight only when held with its axis at 10°, that is, nearly horizontal, and precisely in the meridian indicated first by the ophthalmometer. Thus it would have been safe to have given at once the lens which was indicated by the ophthalmometer.

I prescribed for reading R. — 0.50 cylinder axis, 10°;

[1] Abstract of a paper read before the Oregon State Medical Society, June, 1892.

[2] Refraction and Accommodation of the Eye, p. 320.

L. — 0.25 cylinder axis, 180°. These have proven satisfactory after six months' use. In this case, I do not believe that as long as there was spasm of the accommodation, the most expert oculist could have correctly diagnosed the 0.50 of astigmatism with the ophthalmoscope alone. I now only use atropia when there is pronounced spasm of accommodation which persists in spite of ordinary rest, and rely mainly on retinoscopy (shadow-test) to get the refraction of the meridian of lowest refraction. When there *is* pronounced spasm, all fan-tests, the ophthalmoscope, and retinoscopy will mislead.

Hysteria and malingering may also be detected by the ophthalmometer. Of the latter I lately had an amusing example. A gentleman brought me his daughter, about twelve years of age, who complained of pain, and that she could not see the blackboard at school. Her vision without glasses was $\frac{1}{10}$ only in each eye. By shadow-test and ophthalmometer no astigmatism or error of refraction could be detected. She stated positively that concave lenses improved her vision, and read the small type with them. I suspected malingering, and asking her to read with the right eye (the left being covered) the smallest type she could with the naked eye, she protested that she could only see the LXX of Snellen's chart. I then placed the *empty* frame of a trial-lens in front of the eye, when she glibly read off the XX line! Convicted of deceit, she admitted that she wanted glasses because a fellow school girl wore them!

When no astigmatism is found by the ophthalmometer, I have always found astigmatism against the rule by the ophthalmoscope, retinoscopy, and other tests. Thus: C——, aged nineteen, consulted me, stating that for six months his eyes pained when reading and writing. Vision R. and L. = $\frac{1}{20}$. Javal gives R. and L. no overlapping, and hence no astigmatism. Vision: R., with + 0.75 cyl. axis, 170° = $\frac{1}{6}$; L., with + 0.50 cyl. axis, 180° = $\frac{1}{6}$. With these for reading, all asthenopic symptoms disappeared.

There is another application of this remarkable instrument not mentioned by those who have written of it. It is to indicate the cylinder which will improve vision when there is irregular astigmatism. A man whom I cured of chronic trachoma complicated with dense pannus of the right cornea six years ago, and who lost all useful sight in the left from a corneal scar, came to me a few weeks ago to see what I could do to help his right eye with a glass.

I had not seen him for six years. I found the right cornea free from infiltration or scar. Convex spherical lenses improved vision to $\frac{1}{10}$. The ophthalmometer showed a high grade of irregular astigmatism, the images crossing and overlapping in several meridians. Their bases, however, were tangent only at 60 and 150, and the lower steps touched at 60, and the overlapping was complete at 150, indicating 6 D of astigmatism. With 2.00 spherical, 4.50 cylinder; axis, 150, V. was $\frac{1}{20}$ nearly, the patient reading some of the letters of the XX line. He was much pleased to find now that with a properly ground lens he could once again read with comfort. This is a notable instance of the value of the apparatus, because, owing to the irregularity of the facetted corneal surface, the patient could not indicate to me what lines on the fan were clearest, or clear at the same time; he seeing several clearly at the same time which were not at right angles to each other, and had I depended only on the usual chart-test we would have spent weary hours of testing with lenses.

It is an error to suppose that, while the instrument is not difficult to use as far as finding the principal meridians is concerned, it is not necessary to acquire skill in its use, or to make correct inferences from its results; but it is rank error to assume that because mistakes are made at first by those who employ it, or rarely, that it is too complicated or difficult of manipulation for the office.

Great credit is due to Drs. S. W. Burnett and H. D. Noyes, who were the first in America to write emphatically in its favor and give their results; still greater credit is due to the two distinguished men who have given us a practical instrument for the consultation room. But after all is stated, we unite to honor von Helmholtz, for every result is due to his genius and labor.

A NEW VAGINAL IRRIGATOR.

By CHARLES GETZ, M.D.,

BALTIMORE, MD.

In treating those disorders of females where thorough flushing of the vaginal passage is of prime importance, I have often been forcibly reminded of the incompleteness of the act due to mechanical inefficiency of the instruments employed. All the well-known hand and fountain syringes are open to two serious objections: 1. They do not distend the vaginal passage enough to allow the water to come in contact with the numerous folds, or rugæ of the mucous membrane. 2. They deliver so small a stream of water that it amounts to very little as a cleansing douch.

Acting upon these all-essential requirements, I have devised the vaginal irrigating tube figured in the accompanying cut. This instrument works perfectly and in all conditions; when thorough flushing of the vagina is required it will supply a long felt want. The irrigator is especially intended for married women, and those who from the necessity of gynecological examinations are minus the hymen. The irrigator is made of metal, nickle-plated, is very strong and can be kept perfectly aseptic.

As a matter of economy to some, the instrument will also be made of glass.

The vaginal part of the irrigator is one inch in diameter and four and a quarter inches long. It is slightly curved antero-posterior by thus accommodating the natural curve in the vagina better than the straight tubes of the syringes now in use. The anterior surface is beveled off as the apex is approached, thus allowing the irrigator to be inserted well up in the posterior cul-de-sac.

The terminal portion is perforated by twenty-four apertures which equal in their delivery the amount of water supplied by a half-inch pipe.

The handle of the irrigator is three inches long and half-inch internal calibre. It is supplied with a hook on the back for hanging the instrument on the rim of the reservoir when not in use.

The irrigator is connected with a tin reservoir of two gallon capacity by a flexible rubber tube also of half-inch internal calibre.

Thus it will be seen that the irrigator receives a column of water half an inch in diameter, and distributes the same through its twenty-four apertures against the cervix and upper vaginal region, gently or forcibly in accordance with the height of the reservoir above the hips of the patient.

The vaginal passage being moderately distended by the irrigator, its mucous folds receive a most thorough cleansing by the large volume of water as it passes outward. I have found that an elevation of one foot is enough to secure a good flow from the reservoir, while three feet never need be exceeded.

The tube is fitted with a spring valve by which the patient can turn the water on or off at pleasure. For the neat workmanship shown in the construction of the irrigator I am greatly indebted to Mr. Frank Arnold, of the firm of F. Arnold & Sons, Baltimore, Md.

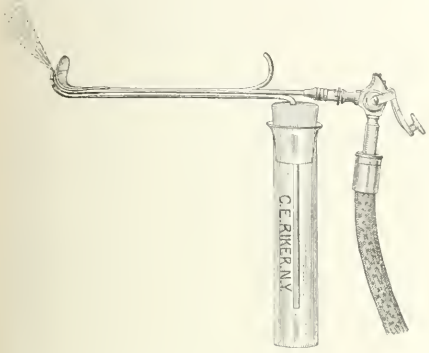
A COMBINED POST NASAL SPRAY AND PALATE RETRACTOR.

By WILLIAM P. BRANDEGEE, M.D.,

CLINICAL ASSISTANT POST GRADUATE HOSPITAL AND MEDICAL SCHOOL, THROAT AND NOSE DEPARTMENT; CLINICAL ASSISTANT MANHATTAN EYE AND EAR HOSPITAL, THROAT AND NOSE DEPARTMENT.

THE difficulties and annoyances met with, incident to spraying out the post nasal space, are very familiar to those who are interested in the treatment of disease in the throat and nose.



The above cut illustrates an instrument, a combined post nasal spray and palate retractor, which was devised to overcome some of these difficulties in cleansing or medicating the vault or the posterior wall of the pharynx.

The operator utilizes his left hand to hold down the patient's tongue with a tongue depressor, while his right hand is employed to introduce the retractor behind the velum, to drag it forward, thus forming the space for the up spray, and to manipulate the cut-off.

The advantages offered in the use of the instrument are manifest in that 1, the operator does not have to depend upon the patient to hold down the tongue; 2, the velum is drawn forward and cannot contract upon the posterior pharyngeal wall; 3, the spray is turned on at the time the velum is drawn forward, and so has a free opening to reach the vault of the pharynx; 4, the discomfort to the patient is reduced to a minimum. The finger-piece gives a resistance point to expend the force necessary to drag the velum forward, and the retractor-blade is made of German silver, so that it may be bent to the angle desired, and is solid, so as to prevent any injury to uvula or velum palati.

The curve of the spray-tube follows closely that of the retractor-blade.

Water or oil solutions may be used in the spray, and I have found the instrument very convenient for spraying cocaine when it was desired to produce local anæsthesia preparatory to operative procedures in the vault of the pharynx.

I am indebted to Mr. C. E. Riker, of Broadway and Thirtieth Street, for his skilful work in the embodiment of my ideas into the instrument which is presented.

36 WEST THIRTY-THIRD STREET.

Pruritus Vulvæ.—The following wash has been found useful by Dr. Bulloch, in cases of pruritus vulvæ:

℞. Aluminii nitratis..... gr. xxiv.
Aquæ..... ʒ iv.
M. Sig.: Wash the parts once or twice a day, and use also as a vaginal injection.—*N. E. Medical Monthly.*

Dislocation of the Jaw.—Monteggia reports the case of a woman who dislocated her jaw while endeavoring to remove with her fingers a small lemon-seed which had become lodged between the last two molars. She had probably weakened the jaw by over-use.

A COMBINATION TEST-CARD.

By D. W. HUNTER, M.D.,

NEW YORK.

THE facility with which many persons, particularly bright children, memorize the ordinary test-cards often makes it difficult to determine whether the patient is really reading the letters or repeating them from memory.

The combination test-card was designed to overcome this difficulty and at the same time provide a compact and convenient set of test-letters. The letters are arranged in rows, as on the ordinary test-card, but instead of using a card the letters are placed on revolving, horizontal bars set in a frame, each bar having four sides. The bars are readily turned by buttons at the side of the frame. There are nine of these bars corresponding to the nine rows of letters from CC to X, inclusive. As each of the nine bars has four rows of letters, one on each side, the arrangement provides for thirty-six rows of letters in the space of an ordinary test-card, nine rows being visible at the same time. A quarter turn of two or three of the bars completely changes the appearance of the card, and the number of possible combinations of thirty-six rows of letters, taken nine at a time, is almost endless, running into the millions.

By placing two sets of these revolving bars side by side

in a frame, provision is made for German letters, pothooks, figures, and card-spots.

The frame, which stands on the floor, makes a convenient rack on which to hang any cards one may wish to use, provision being made for the cards for testing astigmatism above, while the lower portion furnishes a convenient receptacle for extra cards. The back of the frame

could be utilized as an easel for a black-board, the whole taking up very little floor-space and capable of being easily moved about to take advantage of the varying light.

I am indebted to Messrs. GaNun & Parsons, Opticians, for their aid and hearty co-operation in the construction of the apparatus.

Subcutaneous Injections of Thyroid Extract as a Remedy for Myxœdema.—The belief in the importance to the animal economy of the presence in the normal state of such bodies as the thyroid, supra-renal capsules, etc., is steadily gaining ground in this centre of medical activity. That organs unprovided with excretory ducts do form some product which is reabsorbed into the blood is proved by the disastrous effects following their removal. The development of myxœdema in persons whose bronchocelic thyroids have been removed is a phenomenon familiar to all practitioners of medicine. It is further proved by the experiments of Hédon, of Montpellier, already communicated by me to *The Lancet*, that the continued vitality of a grafted portion of the pancreas insures the animal against diabetes, even though the intra-abdominal portion be excised. That condition is, on the contrary, induced by the total ablation of the normal but evicted pancreas, and also by the destruction of the grafts, the intra-abdominal portion being left *in situ*. As regards myxœdema, Professor Bouchard[1] reports two cases recently treated by him at the Charité Hospital by means of injections of thyroid juice. Both patients were females, and the improvement was, in each instance, extraordinarily rapid.—*The Lancet*.

Education as a Therapeutic Measure.—A paper on "Education in the Treatment of Nervous Girls," read recently by Dr. Louise Fiske Bryson before the Social Science Association, contains the following ideas: There are three varieties of nervous girls: Those born with an originally unstable nervous system; those who have what is known as the insane temperament, yet who never become insane; and those who suffer from some definite form of nervous disease. Their education, to be practical, must be in directions of universal interest that will last a lifetime, and endure when everything else fails or is outgrown. These permanent interests are four: General literature, history, social economics, and objective science. Through good books, chiefly, is contact with superior minds made possible. History, when properly presented, breaks down prejudices, does away with intolerance, leaves the mind open to conviction, and teaches it to suspend judgment. Modern economics inevitably lessens discontent as it reveals sources of social happenings, and affirms anew the vitality of the spirit of the times. The study of science calls out and directs powers of observation and sharpens in a pleasant way the faculty of discrimination. This may be seasoned with something of art and a taste of foreign languages. But in point of health, unless ability is phenomenal, and therefore in itself an energizing power, the outlook is far from hopeful when the æsthetic side predominates.

As nothing in nature requires so much oxygen as a nerve, the necessity of outdoor sport and exercise is at once apparent. The bicycle has distinct value; also rowing, swimming, riding, tennis, old-fashion croquet, and sometimes cricket. Dancing and bowling develop strength and grace; and fencing and boxing are good for boys and girls alike. Housework constitutes an admirable series of home gymnastics. The education of the skin is a matter of great importance. Water is a means to this end, in the form of a douche, shower, or pack. The cultivation of athletics is a hopeful fashion that is rapidly becoming a custom. If girls were examined, their deficiencies explained, and rational gymnastics prescribed, purer blood, firmer muscles, sounder heads, and more satisfactory physiques would result. In childhood should begin instruction in the art of dressing well, according to the strictest conventionality. Theoretic dressing is always dangerous, especially for those who have weak nerves. Whatever makes them appear different from others, whether more picturesque or ideal, must be gently but firmly frowned down. Anything approaching a "costume" is to be deprecated for nervous girls, as it attracts attention and deepens self-consciousness. The best thing that can happen to a nervous girl is to be liked. To this end the guardians of any such child should instil early into its mind the spirit of self-denial that has for its outcome graces of speech and movement, silence and self-command, pure tones and distinct utterances, together with tact and good spirits. The effort necessary to be cheerful and sympathetic, in spite of physical weakness, lessens introspection and mental indolence, and rouses activities that might otherwise remain dormant.

Shorter school-hours, more time in the open air, more housework and accomplishments requiring bodily activity, good manners and conventionality in dress, the study of objects close at hand, familiarity with the recorded thoughts of mankind, a knowledge of the principles that underlie the social condition, the art of government, and practical politics, together with strict regard to bodily health and sufficient rest, are some of the elements necessary to happiness, efficiency, and power to please in the nervously weak. Their shrunken individuality must be expanded by means at once directed toward repression of egotistic instincts, toward the enrichment and orderly arrangement of ideas, and through multiplication of acts and external relations toward the energizing of the insufficient or diseased will. To outline definitely this special education is to introduce a factor in therapeutics capable of wide-spread influence and permanent good. To enforce it in detail is to secure conditions that bring about poise and self-reliance, and are favorable to the development of quality and fibre essential to complete living.

SUGGESTIONS RELATING TO IMPROVEMENT OF QUARANTINE.[1]

By STEPHEN SMITH, M.D.,

NEW YORK.

THE continued presence of cholera in Western Europe and the recent arrival in New York Harbor of several steamships on which the disease appeared during the voyage has awakened a new interest in the quarantine defences of this country. And this interest has been greatly intensified by the occurrences on the arrival of these vessels at the port of New York. They demonstrated the total incapacity of the most important quarantine in the United States to meet the emergencies that may arise at any time when travel and commerce are unimpeded. The apprehension which now prevails that there will be a recurrence of the epidemic in the seaport towns of Europe next season, and that the quarantine at this port will prove ineffectual, both in its appointments and management, to prevent the introduction of the pestilence into this country, will doubtless lead to efforts to secure State and national legislation, designed to remedy existing defects and evils. Whatever efforts are made should be based on principles established by sanitary science and recognized by the medical profession. It seems eminently proper, therefore, that this Association, representing the profession of the State in which the chief quarantine is located, and by which it was established, is maintained, and managed, should at this time consider this great public health question, and express an opinion which will tend to guide legislative action. In this view the following paper has been prepared.

The question of improving the quarantine of New York may be considered, first, in respect to the enlargement and perfection of the present establishment; and, second, with reference to supplementing or superseding it by a national quarantine.

The propriety of endeavoring to place our present quarantine in condition to meet the demands that may be made upon it early in the next season may be seen when we consider its construction and surroundings. The establishment is located on two artificial islands in the harbor. They were constructed at great expense by the State, owing to the intense opposition of the people to the former location on Staten Island. This opposition was so violent that the former buildings were burned, and the Legislature passed an act forbidding the location of quarantine on Staten Island and on Long Island. There was, therefore, no other alternative left to the State but to construct these islands. Like all work of this kind the construction proceeded slowly, and the expense was very great. When finally completed, the quarantine consisted of two islands of limited capacity, one for the care and observation of well persons removed from infected ships and the other for the care and treatment of the sick. Provision was made for but a single contagious disease. The capacity of these islands was for the proper care of a single infected steamship, with not to exceed one thousand passengers—of whom two hundred and fifty might be "suspects," and seven hundred and fifty well, but who had been residents of this so-called infected ship. The arrival of two or more such ships in quick succession would, as was proved in September last, create such a congestion as would render it impossible to remove the well from the ships. The travelling public must not only be subjected to great hardships under such circumstances, but they would be exposed to the danger of contracting the disease prevailing on shipboard while at quarantine.

The only method of rendering our quarantine adequate to meet the demands of the increasing travel and commerce at this port is to enlarge its area. There should be ample surface area to extend its accommodations to a limit equal to the largest demand that can be made upon the establishment. But how is this enlargement to be effected? It is impossible to occupy any part of the shores of the bay belonging to the State, or any part of Long Island, for the purposes of a quarantine. Not only does the law forbid such occupation, but public opinion is so firmly fixed and determined that it will be impossible to secure necessary legislation to that end. The only method of enlargement is, therefore, by increasing the capacity of the present islands, or by the creation of new islands. It is only necessary to state these facts to prove that there is no possibility of relief from the present situation by attempting to improve adequately the present quarantine. The State will never be induced to incur the expense necessary to such an undertaking. Nor, indeed, should it be required to create and maintain a quarantine of the dimensions and cost which will meet the present and future wants of the country. This is an obligation which now devolves upon the national Government, and it should be required to assume that obligation at once.

Fortunately, all of the conditions are favorable for the immediate organization and equipment of a national quarantine at this port. Sandy Hook, which belongs to the general Government, is, according to recent advices and events, immediately available for such purposes.

There are ample unoccupied lands which afford the necessary area for such an establishment, whether to meet present or any future requirements. The location can be thoroughly adapted to the wants of commerce, the anchorage is good, and the surface area and soil are all that could be desired for the arrangement and construction of the necessary buildings. Here can be created a station for infected ships which will admit of the immediate removal of the sick and well from on shipboard, whatever their numbers may be. The sick can be taken to hospitals adapted for a variety of contagious diseases, and the well or "suspects" can be separated into any required number of isolated groups in pavilions where they may have every convenience necessary to their comfort and health. Here also can be warehouses for the reception, cleansing, disinfection, and ventilation of every form of baggage and every variety of cargo. And, finally, here can be maintained, in a state of constant efficiency, every agency essential to the rapid cleansing of an infected ship. With such a station in this harbor there would be no need of any proclamation of a twenty days quarantine for the purpose of restricting immigration. Nor would there be prolonged detention of passengers for observation, nor the withdrawal of ships from commerce for long periods for proper disinfection.

Two questions will naturally arise in the minds of those who may not be familiar with recent national legislation in relation to the quarantine system of the United

[1] Read at the meeting of the New York State Medical Association, November 17, 1892.

States: 1, Is it practicable to secure the location of a national quarantine in this harbor? and, 2, if such a quarantine is established, will it not conflict with the State establishment?

The first question seems to be already answered in the affirmative. The Government has taken the initiative, and laid the foundations of a station that can rapidly be enlarged and adapted to supply every want and condition of the most perfect modern quarantine establishment, and in time to meet any emergency during the next season.

It may be objected that the camp created on Sandy Hook by the Government is a temporary expedient to meet an emergency, and that a permanent quarantine cannot be secured without legislation by Congress that would involve contention and delay. Happily, this is not true; but, on the contrary, the creation of a quarantine in New York Harbor and its complete equipment by the general Government would be simply an extension of the policy which it has pursued for the last decade. A brief review of the course which the Government has followed during that period in regard to the protection of the United States against the introduction of contagious and infectious diseases will show not only that the establishment of a national quarantine at New York would be in accordance with its present policy, but will prove that the Government is under obligation to create such a station for the benefit of the commerce of the North Atlantic coast.

In 1880 the National Board of Health, after the suppression of the great epidemic of yellow fever of 1878–79, in the Mississippi Valley, began to inaugurate methods of preventing in the future the introduction of contagious and infectious diseases into this country. A careful inspection was first made of the quarantines of the United States which, at that time, were all State and municipal organizations. It appeared from this inspection that our seaboard and Gulf quarantines were, with one or two exceptions, utterly worthless. As a rule they were maintained as a part of the local or State political machinery, with no pretence even of performing any useful public service. The best establishments were deficient in area, in buildings, and in appliances for the proper treatment of infected ships.

The plan adopted by the National Board to meet the exigencies found existing was to supplement these local quarantines by a series of national quarantines, called Refuge Stations. These stations were to be, and have been, located at such points along the coast as would be most convenient for infected vessels bound to ports in the vicinity. In pursuance of this policy stations have been created for the Gulf ports, one at Chandeleur Islands, and another at Key West; for the South Atlantic ports one is located at Blackbeard Island, Sapolo Sound, off Savannah; for the Middle Atlantic ports, one is at Cape Charles and another at the Delaware Breakwater. In the same manner for the Pacific ports there is one at San Diego, another at San Francisco, and a third at Port Townsend, Puget Sound. The only part of our seaboard that has not been supplied with these stations is the North Atlantic.

These Refuge Stations form a series of exterior quarantines, which are at all times to be maintained in a state of the greatest efficiency. They occupy isolated positions, generally insular, and have ample areas admitting of any necessary isolation of passengers and their segregation into groups. They are to be fully equipped with every appliance required for the quick restoration of an infected ship to its service.

In practice, any infected or suspected vessel bound for a port in the district in which a national quarantine is located would first proceed to this station and perform quarantine before it attempts to enter the port of destination. No local quarantine officer should allow such a vessel to enter the port which does not bring a certificate of having performed quarantine and been satisfactorily cleansed and disinfected at the national station.

This quarantine system finds its best illustration in England. The coast of that country is divided into quarantine districts, and for each district there is a single well-equipped government quarantine. To this station every infected vessel must proceed and perform quarantine before it attempts to enter any port of the district. The great value of this system is seen in the thorough protection which it affords a country against the introduction of a foreign pestilence. It creates two lines of defences, an exterior, where the infected vessel and passengers receive prompt and efficient care and treatment, and an interior, at which every vessel, whether infected or suspected, is intercepted and turned back to the Government quarantine.

Again, it insures at proper places along the entire coast thoroughly efficient quarantines, always ready for and capable of meeting any emergency. The importance of this fact will be recognized when we examine local quarantines in the absence of any alarm in regard to an epidemic. With rare exceptions they are allowed to go to decay, owing to the great cost of maintaining them in a state of efficiency. Perhaps the quarantine at this port has been more liberally sustained by the State than any similar establishment in the United States, and yet when a cholera-infected ship suddenly entered the harbor in 1887 it was wholly unprepared for the occasion. Though the next legislature granted a large appropriation, and very extensive additions and improvements were made, yet on the arrival of the recent cholera ships much of its equipment was found too defective to be of any service.

In regard to the relation of the local to the national quarantines it is apparent that they should act in harmony. There should be no friction. The local quarantines should continue to immediately guard their respective ports against the introduction of any infectious or contagious disease, and two or three might perhaps be relied upon to quarantine vessels having the milder forms of these affections on board, but they should depend upon the national establishment to care for vessels bringing cholera or yellow fever, or to meet any emergency.

If any legislation by Congress were necessary to place the national quarantine stations in their proper positions, it would only be necessary to pass a law dividing the seaports into quarantine districts, and require every infected or suspected vessel, bound to any port, to perform quarantine at the national station for the district in which the destined port is located. The same purpose would be accomplished if Congress would pass the following section of a bill reported by the Committee of Commerce and Manufactures to the House of Representatives, as early as May 7, 1796:

"Be it enacted, etc. The President of the United States be, and is hereby authorized to direct at what place or station in the vicinity of the respective ports of entry within the United States, and for what duration and particular periods of time, vessels arriving from foreign ports and places, may be directed to perform quarantine."[1]

[1] One of the most vigorous supporters of this bill was Mr. Smith, of South Carolina. He said: "If this question be a mere question of acquiescence in the State laws there might be a propriety in the Federal Government overlooking those laws; but it was essentially connected with the powers of Congress on an important subject. He had been surprised to hear gentlemen assert that this subject was not of a commercial nature. The gentleman from Virginia had said diseases were not articles of importation, or, if they were, they were contraband, but gentlemen must know that importations of all kinds were under the regulation of Congress, and contrabands as much as any other. Consider how epidemics, imported, affect the United States at large. They do not merely affect the city where first imported, but they obstruct the commerce of all others; they not only embarrassed the commerce, but injured the revenues of the United States. Another point of view in which it had an effect: the laws regulating the collection of imports were counteracted and obstructed by the laws regulating quarantine, and would any gentleman say that a State legislature had the power to contravene the act of the Federal Government, to obstruct all of the laws by which it collects its revenues. It had been said that this subject could be better considered in each individual State than we could possibly settle it. Who are we? Are we a foreign government? Gentlemen had already forgotten their arguments on former occasions when speaking of the power of the

The quarantine at the port of New York, in the event of the creation of a national station at Sandy Hook (or, indeed, in any event), ought to be placed under the jurisdiction of the Health Department of the city of New York, which should be made responsible for its proper management. Its officers and employees should be appointed by that department, and the chief officer should be the Sanitary Inspector of the Port. The laws relating to the government of quarantine should be repealed, and the Health Department should be authorized to make such rules and regulations relating to the inspection of vessels, their proper care, and the details of administration of this sanitary service of the port as it may from time to time deem necessary. Such a change in our quarantine establishment would of itself be an immense improvement, for it would be brought under the immediate supervision of a department which has a vital interest in its efficient and successful management.

SUPRAPUBIC HYSTERECTOMY AS PERFORMED WITH A SET OF NEW INSTRUMENTS DEVISED FOR THE PURPOSE.

By J. S. PYLE, M.D.,

CANTON, O.

I DESIRE in this article to review the field of hysterectomy, introducing new features and a new set of instruments designed as an aid in the successful performance of the operation.

Hysterectomy as made per vaginam is unsurgical and should be discouraged. The operator cannot foresee danger likely to be encountered in this class of operations; and with the most favorable cases possible at our command the vaginal route cannot be approached in any other than a haphazard manner. An old operator once said to me, "Vaginal hysterectomy is all guess-work." Since then experience has taught me to entertain the same view. In vaginal hysterectomy only the most favorable cases should be undertaken, while in the supra pubic operation cases that would be entirely excluded can be successfully operated upon. In carcinoma of the cervix no one can, through an examination of the patient prior to the operation, form any definite conception of the extent of the carcinomatous infiltration of the broad ligaments and surrounding tissues. This can be made out with a considerable degree of satisfaction in the abdominal operation, where the structures are thoroughly exposed and an ocular demonstration made.

Old inflammatory adhesions, immobilizing the pelvic organs, place vaginal hysterectomy beyond a possible hope of success. The same can be said of advanced cases of carcinoma where the uterus has undergone enlargement. The greater the hypertrophy the more difficulty attends removal. Anatomical differences also influence the success of this method of operating. A narrow vaginal canal and resistant tissues compromise the field of operation and increase the difficulty. With all the conditions favorable, not a step of the operation can be entirely satisfactory. Strict antisepsis is out of the question. Ligation of the bleeding vessels and uterine ligaments is accomplished in a chance manner. The ureters and knuckles of intestine may be injured or included in the ligatures. The closure of the vaginal roof, when attempted, is always imperfect. On the other hand, as a plea for the suprapubic operation, I offer the following observations: The operation can be made in a surgical manner, every step intelligently prosecuted, and the greatest chances offered the patient for recovery.

I proceed, after minor preparation of the patient has been attended to, by thoroughly cleansing the vaginal canal with antiseptics, and if the operation be performed for the removal of a cancerous cervix, the cervix is scraped of all its loose particles and irrigated with a 1 to 1,000 bichloride solution. The cervical canal is then packed with minute tampons of cotton-wool saturated in a solution of bichloride. This is to prevent any escape of infectious products while the organ is being removed through the peritoneal cavity. The abdominal wall is prepared in the usual way, and the patient is anæsthetized and placed on the table. Five assistants are required; two to assist directly in the operation, and the remaining three to take charge of the anæsthetic, sponges, and instruments. Strict antiseptic precautions are observed throughout the operation. The peritoneal cavity is opened through the linea alba, just above the symphysis pubis. The length of the incision required varies, depending upon the mobility of the uterus, but as a rule it should extend from the umbilicus to the symphysis. Aside from a few minor details, up to this juncture all suprapubic operations are prosecuted alike. Surgeons differ as to the manner of releasing the organ from its attachments, the closure of the pelvic floor, and the disposition of the pedicle, when one is left.

Eighteen months ago—independent of any other operator—I conceived my ideas of the entire removal of the uterus by the abdominal route. Eastman, it appears, had entertained similar ideas, and superseded me in making them known; but while our operations are essentially the same, they differ in the technique of their performance. I aimed at rapidity, and to achieve this designed a set of hysterectomy instruments, which were submitted to Messrs. Tiemann & Co. about eighteen months ago, and in the course of a few weeks they were completed. The operations as performed by Schröder, Pean, Byford, and their disciples, consist in the amputation of the uterus through the neck, and retaining a stump as a key to the

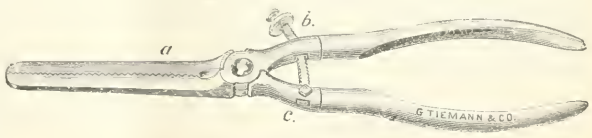

FIG. 1.

support of the pelvic contents. These methods are limited to the removal of the uterus for diseases affecting the body and fundus, and are not applicable to cases of cervical cancer.

I cannot see the importance of retaining a stump in any case. The danger arising from hemorrhage, which Byford has tried to obviate, makes it desirable to completely remove the neck. The argument that it supports the pelvic contents is untenable. I should be inclined to hold the opposite view; that its inherent weight would encourage prolapse of the posterior vesical wall; while, on the other hand, in the removal of the cervix the recto- and vesico-uterine attachments are united, and the effect is to tighten rather than to relax the pelvic floor. Furthermore, it cannot be held that the removal of a weight having a natural tendency to produce prolapse will increase that tendency. The reasoning is fallacious.

FIG. 2.

Supporters of this idea also maintain that to remove the cervix exposes the patient to increased risks of septic infection. I cannot agree with this view, inasmuch as the closure of the peritoneal cavity can be made as perfect in

House; they could then do anything and everything, and the people looked up to them alone for protection. If the subject was vested in the general Government it was their business to protect the health of their fellow-citizens as much as their property; because if the performance of quarantine was neglected such neglect naturally tended to affect the lives as well as the revenue and commerce of the citizens throughout the United States. He, therefore, thought it a subject perfectly within the Federal jurisdiction."

the absence of the stump as with it, and the healing process takes place even more rapidly, owing to the exclusion of the cervical canal as a source of infection.

In my method, after the abdomen is opened, four pair of clamps, after the style of Fig. 1, are clamped upon the broad ligaments. The jaws of the clamps are long enough to seize the ligament from the top to its lower border, the serrated edges and nicely juxtaposed surfaces securing perfect hæmastasis.

Figs. 3, 4, and 5.

At *b*, in Fig. 1, the handles are separated from the clamp; at *c*, a catchpin, provided with a thumb-nut, passes through the shoulders of the levers and is used to fix the jaws whenever the handles are compressed.

The handles shown in Fig. 2 are separated from the clamp; they are universal, and are removed as soon as the clamp is fixed upon the ligament. This reduces the length of the instrument and economizes the necessary space.

Fig. 6 shows all the clamps adjusted and the uterus elevated above the pelvic brim with vulsellum forceps, and held by an assistant. In applying the clamps two pair should be placed upon the ligaments, one on either side of the uterus, as close to the organ as possible, and the remaining two removed from these a short distance, leaving space enough between the clamps to divide the ligaments with scissors, as is shown at *a* in the illustration.

Owing to the fact that the uterus is made pendulous and less traction is necessary, the clamps should be applied and the ligaments divided before the organ is lifted from the pelvis. When this step is completed the uterus is drawn through the abdominal incision, the hypogastric arteries ligatured (using the right-angled needle shown in Fig. 4), and a separation from the vaginal roof effected by cutting laterally on either side from the front to the rear of the cervix. The uterus, being freed, is removed, accompanied by two

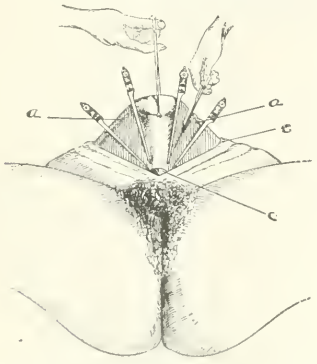

Fig. 6.—*a*, Point of division of broad ligaments; *c*, top of bladder; *c*, border of abdominal wall.

pair of clamps attached to the proximal ends of the ligaments. Fig. 7 shows the pelvic contents after the organ has been taken away.

In this illustration the incised pelvic floor is held up by two assistants with two tenacula, and the needle is Fig. 3, shown in progress of making the first suture. The manner of making the sutures is important. No. 34 silver wire is used, cut in pieces six inches long, each piece being armed at each end with a loop of No. 8 silk thread. The loop of silk is dropped into the open eye of the needle shown in Fig. 3, which is thrust through the pelvic floor into the vagina about a quarter of an inch from the border of the incision. The loop is then removed from the eye and the needle withdrawn, and the opposite end of the suture treated in like manner. When both ends of the wire have been secured in the vagina, the ends should be given a few twists to prevent slipping. All sutures are adjusted in like manner from before backward, separated from one another about a third of an inch. The broad ligaments should then be ligated in three parts

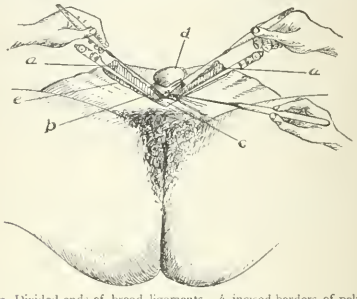

Fig. 7.—*a*, Divided ends of broad ligaments; *b*, incised borders of pelvic floor; *c*, top of bladder; *d*, rectum.

with No. 8 silk (using needle shown in Fig. 5), the clamps removed, and the pelvic floor closed by twisting the silver-wire sutures through the vaginal canal. An ordinary bivalve speculum is used to open the vagina.

Fig. 8 shows the pelvic contents at the close of the operation, before the abdomen is closed.

Lastly, the abdominal toilet should be made the same

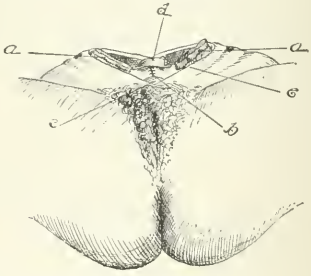

Fig. 8.—*a*, Ligated broad ligaments; *b*, coaptated pelvic floor; *c*, incised abdominal border; *d*, rectum.

as in other abdominal operations, and the vagina packed with bichloride gauze impregnated with iodoform. Extra precautions to secure rapid closure of the peritoneal cavity may be taken by uniting the incised peritoneal borders of the pelvic floor and abdominal wound with small animal sutures. This is optional, and should be left to the judgment of the operator at the conclusion of the adjustment of the silver-wire sutures directed into the vagina. Usually the coaptation is so perfect that this is unnecessary. For this method of making hysterectomy I claim rapidity, thoroughness, wider application, and an ideal surgical operation.

68 West Tuscarawas Street, August 10, 1892.

Boro-Borax is a new preparation, discovered by Jaenicke, which is formed by mixing equal parts of borax and boric acid in boiling water. When the water cools the greater part of the substance crystallizes out. Its antiseptic and therapeutic properties resemble those of boric acid, but it has a neutral reaction and is much more soluble. At ordinary temperature 16 parts of boro-borax dissolve in 100 of water; at 100° F. 30 parts dissolve in 100 of water; while boiling water dissolves seventy per cent.

DIPHTHERIA AND ITS RELATIONSHIP.

An Antithesis to the Modern Doctrine of Microbes and Bacteria, from Original Researches.

By A. LIEBIG, M.D.,

NEW YORK.

When first I began, five years ago, to take a deep interest in the etiology of diphtheria, the formation of the membrane was the first point which particularly attracted my attention. The variety of explanations of the manner of the formation of this membrane alone gives the observer sufficient matter for meditation, and he must, premising a sufficient knowledge of medicine, chemistry, and natural sciences, come to the conclusion that here is a doctrine constructed whose deeply lying contradictions and errors may be traced step by step. To give myself a clear perspective, hence, I have determined to grasp the whole human being at the given moment—that is, to take everything into the scope of my investigation that might be a carrier of the cause of disease, as, for instance, the saliva, urine, the excrements, the vomita, the blood, and the membranes, of course all taken ante mortem. I began under the mistaken idea that these researches could be concluded in four to five weeks, and that then I would be able to give myself and my interested friends a lucid explanation on their results. However, after I had once started on the inductive way and attempted to solve and answer the questions that suggested themselves, I saw before me a task which, for complication in respect to etiology, physiology, pathology, chemistry, and natural philosophy, left nothing to be desired. I stood before a seemingly endless problem. Periods of stagnation occurred, but the more difficult the problem became the more energetically did I set my will to tear away the thick veil that nature in its mystery threw over it. My motto was: "I want to find the truth for the sake of the truth, even at the cost of my life."

There passed—shall I tell—five long weary years before I saw light, truth, and terra firma united before me. But this light shows me that I have placed myself in the most direct contradiction of to-day concerning microbes and bacteria as causes of disease. This contradiction I have not labored to find, neither did I desire it. It is here; it cannot be cast out from the world. We must calculate with this new factor, not in my interest, but in that of all humanity. I do not deny the existence of microbes or bacteria, but I do deny their causa primaria in the introduction of the disease. In twenty-five cases which I have systematically investigated I found microbes, bacilli, coccí, mycelia, thallophyta, spores, trichomata, palmelaceæ in various forms, but with these a heretofore unknown plus, which must not be omitted in this calculation. This unknown plus is composed of spirals, ova, granules, episperm. These factors form a constant basis in the disease, and hence they must be the real, the fundamental cause of diphtheria, while the hitherto supposed true causes are shown to be secondary phenomena.

On the results of my investigations I have constructed twelve theses, which I am willing to defend publicly, not through vanity or rash enthusiasm, but through the desire to benefit all mankind. The greatest inducement was my own free will, hence the work is independent, unconstrained, uninfluenced by the current idea of the day. Here speaks Nature in her might, pure and unadulterated. The language of Nature is always truth, and this I wished only to interpret for my contemporaries and posterity in my work. I wished to present diphtheria, this dreadful destroyer of children, in persona ipsa, to the anxious mothers and to the profession.

The Theses.—I. Diphtheria is caused by a living organism. This may be either winged or unfledged—infectio originalis.

II. The constituents of true diphtheria consist in spirals, ova, granules, episperm.

III. The granule is an albuminoid body and a toxicon katexochen. It is a trivalent, albuminoid animal ferment.

IV. The episperm is not a bacterium. It is the intrinsic, living attribute for the to-be-fructified ova. Its destination requires an exceedingly high degree of activity.

V. The so-called membrane is positively only a local manifestation of an eliminative and exudative process, caused by the previous absorption of granules into the blood and lymphatic circulation through the intestinal glands.

VI. The so-called membranes, whether creamy, chamois-like, hyaline, or parchment-like, are chemically and physiologically identical with the factors originally deposited in the intestines and partially their products of separation.

VII. The coexistence of microbes, bacilli, spores, schyzomyceta, mycelia, thallophyta, trichomata, palmelaceæ, and also other cryptogams and microbioses is not to be denied. They increase the intensity of the disease as well as the danger to life, but they are not the cause, neither the causa physica nor the causa excitans.

VIII. On the same basis of reasoning, there is a human and an animal diphtheria.

IX. The central and peripheral phenomena are dependent on the position of the constituents, but particularly on the condition, the quantity, and the translocation of the absorbed granules.

X. Diphtheria is an embryonal, intestinal parasitism, with consecutive local manifestations in the pharynx and larynx, with a decidedly cystic course, and of sometimes apparent hibernating tendency.

XI. The infectio originalis may occur directly or indirectly.

XII. An infectio secundaria is possible by means of the granule and episperm. It has, however, a decided moderation and deviation in its course.

These theses it is my intention to defend in my work against the representatives of bacteriology. For greater lucidity, I give below a short *résumé* of my work on the nature of diphtheria. The causa physica, the punctum saliens of diphtheria is the generative propagation, or the succession of generation of a certain living organism. I am now in possession of this organism, of the spirals, ova, granules, episperm, membranes, etc. The *facit* of the entire inductive work leads to the conclusion that there are metamorphemena which select man, certain mammalia, and also birds as their host, to carry out the alimentation and transformation of their embryonal posterity in this adopted economy, although incidentally and transitorily, yet also compulsorily.

The organism reaches the human economy by means of uncooked food, perhaps also in water, in the form of a small insignificant larva, and here begins the progeneration in the production of ova. But the necessity which compels the host to support and to nourish the ova lies in the linking of the ova to the intestinal glands by means of the spiral. The true reason for this compulsory exhaustion of a foreign economy I believe to be founded in this, that the life of the mother, after having given birth to a future generation in the form of one, two, or three thousand eggs by this intense reproductive power, is at once exhausted. Hence the mother is induced by a natural foresight to secure the ova, as she can no longer herself provide for them otherwise.

This mother, in anticipation of her imminent death, possesses prospective ingenuity for the necessities of her children, for she fastens the ova to the intestinal glands and dictates besides to the respective pension the feeding of the same *à la carte* in the form of an energetic ferment that is the trivalent albuminoid granule. It is not sufficient that the ova can be nourished in the strange economy, but the host is compelled to feed the ova in a fermented way.

Such is the language of Nature, and Nature never lies. For mother and father live in nature in fresh and fer-

menting vegetables, in decomposing flesh, in rotting cadavera, and hence the mother desires that her children already as ova shall be reared and developed to maturity in the foreign economy, but on a fermented albuminoid nutriment. This testamentary devising involves and insures a richly fermented nutrition for the ova, but this decree in the form of the albuminoid granule is the germ of death for the bearer of this predestined support, nutrition, and development, for the granule, being an albuminoid ferment, involves the nourishment of the ova in two forms:

1. *A Gaseous Form.*—The ova get a fermented local respiration in the intestine, introduced by the vegetable local fermentation.

2. *A Liquid Form.*—The ova get a fermented local albuminoid alimentation, introduced by the albuminoid granule in the general plasma fermentation.

The latter form of nourishment has for consequent phenomena: 1. The breaking up of the plasma. 2. The breaking up of the blood-cell and its alluviation in the pharynx. 3. The catarrhal exudation from the eye and nose. 4. The plastic exudations in membrane form in the pharynx and larynx.

That the ova, as her children, shall not remain sterile, however, the mother leaves them thousands of episperm rods for the fructification, which appear almost identical with the bacilli in form and structure. The fructification of the ova occurs by the swarming out of the intensively active episperm rods during the general fermentative periods, with the symptomatically appearing fever-paroxysms.

All other microbes and symbioses appear as secondary, concomitant, aggravating elements, for this can find a firm hold only after the introduced plasma fermentation, as a disturbed equilibrium of the plasma is the absolute necessary basis for the multiplication of the microbes.

First a split up plasma by means of the granule, and then door and gate are ajar for the multiplication of microbe and bacteria. The character of the disease, namely, whether there develops in a given case, diphtheria, scarlatinal diphtheria, or croup, is dependent on the disposition of the constituent elements, which form the natural modus propagandi. If, then, we wish to accurately specify the cause of diphtheria as such, we must say:

1. The propagation of the metamorphemena is the causa physica. 2. The mother, as the state of life, is the causa propria. 3. The spiral, as the chain between the intestine and the ova, is the causa mathematica. 4. The ova, deriving fermented nourishment, the causa postulans. 5. The granule, as the general ferment, the causa excitans. 6. The episperm rods, as the fructifying element of the ova, the causa alterans. 7. The fruits of the creeper plants, as bearers of the germ, the causa medicatrix. 8. The sojourn of the being in the free nature, the causa remota.

The causa physica is chronologically in diphtheria as follows: 1. The albuminoid ferment, in breaking up the plasma, is the causa primaria. 2. The microbis, capable of multiplication only in an altered economy, is the causa secondaria. 3. All the microbioses, as bacilli, cocci, spores, mycelia, undoubtedly only the causa concomitans.

My work explains satisfactorily: 1. Where and why the membrane formation occurs in the pharynx and larynx. 2. How the membrane formation occurs, and of what it forms. 3. Why complications of bronchitis and pneumonitis appear. 4. When and under what conditions metamorphoses occur. 5. The metamorphoses may be: Diphtheritis pallida, diphtheritis scarlatinosa, laryngitis membranosa, laryngitis membranosa crouposa, laryngo tracheitis membranosa.

That the metamorphemena follow this modus propagandi cannot be exclusively shown by medical investigation, for it lies in the province of the entomologists, whose competent decision of my correct or incorrect observation we must first obtain.

On the discovery of this problem I will be able to place in the hands of medicine the proper and fitting key to a large group of internal diseases, as soon as the opportunity is given me for further researches.

111 East Twelfth Street.

EXCISION OF THE INNER TWO-THIRDS OF THE RIGHT CLAVICLE FOR SARCOMA.

By ARNOLD CADDY, F.R.C.S. Eng.,

CALCUTTA, INDIA.

MEMBER OF THE CLINICAL SOCIETY OF LONDON; MEMBER OF THE BRITISH MEDICAL ASSOCIATION; MEMBER OF THE CALCUTTA MEDICAL SOCIETY; LATE SURGEON TO THE CANCER HOSPITAL, LONDON, AND CLINICAL ASSISTANT TO THE ROYAL LONDON OPHTHALMIC HOSPITAL, MOORFIELDS.

Nathaniel N— —, aged twenty-six, a gas stoker by trade, living in Battersea, London, was admitted into the Cancer Hospital, London, January 6, 1892, complaining of a large swelling on the inner extremity of the right collar bone.

He had no family history of malignant disease, and his personal history was that about two years ago he fell from a height and alighted on his shoulder. He sustained no fracture, and he felt but little ill effect from his fall. Twelve months ago he felt that his right shoulder was rather stiff, and then he noticed a small lump growing at the inner end of the collar bone, about the size of a walnut; it gave him very little inconvenience, and he suffered no pain from it. This lump grew slowly till a few weeks ago when it began to grow faster. Sometimes after using his arm a good deal he became more tired than he was wont to do before the swelling came. He has been able to use his arm freely and to do his work well. He at no time had noticed any swelling of the right upper extremity or of the right side of the face. He had not been getting thinner but has always been healthy and strong. He was a fine, healthy looking, muscular, well-developed young man, with very grotesque tattooing all over his body. There was a solid, rather hard, very slightly elastic swelling, situated at the inner end of the right clavicle, firmly attached to the bone and implicating the inner half of it. The external limits were well defined and circumscribed, but below the clavicle it seemed to extend downward rather indefinitely in the substance of the pectoralis major muscle. The surface was smooth, the skin moved freely over it, and the superficial veins were slightly enlarged. There was no tenderness on pressing the growth, and there were no enlarged lymphatic glands to be felt in the neighborhood. The arm could be moved quite freely by the patient. The growth moved with the clavicle, and when the shoulder was pushed forward to the fullest extent the fingers could be pushed down behind the growth. There was no œdema of the right arm, and the pulse was equal in the two radial arteries. The heart and lungs were healthy. Urine clear, acid, golden, sp. gr. 1020; no albumin and no sugar present.

After consultation with my colleague, Mr. Bowreman Jessett, when periosteal sarcoma of the clavicle was diagnosed, I decided to excise the clavicle and the tumor. Accordingly on January 7, 1892, with Dr. T. Johnston English giving ether, and assisted by the house surgeons, Mr. S. D. Willard and Mr. C. P. Le Quesne, I made an incision six inches in length along the anterior border of the right clavicle, meeting at the sternal end with another incision running vertically along the inner border of the sterno-mastoid muscle, commencing on a level with the cricoid cartilage and ending three inches below the sterno-clavicular articulation. The skin having been dissected off the tumor, the clavicular attachment of the sterno-mastoid was divided, the clavicular portion of the pectoralis major muscle was freed from the tumor in the same way. As the outer third of the clavicle was not implicated in the disease, I decided to retain it and remove only the inner two-thirds of the bone. A metal spatula was next passed behind the clavicle at the junction of the outer with the middle third of the bone, and the

bone was sawn through. The bone was then lifted up and the subclavius muscle and the rhomboid ligament were divided by careful snips with the scissors. The inner end of the bone was forcibly turned upward and inward and freed from the surrounding parts. The anterior and posterior sterno clavicular and the interclavicular ligaments were divided and the bone separated from its attachment to the sternum, the fibro-cartilage being removed with the bone. After the removal of the inner end of the bone it was found that a narrow tongue of growth extended downward behind the manubrium to which it was attached, but it did not involve the bone. This was carefully separated and great difficulty was experienced in getting it clear. In doing so the pleura and the innominate vessels were exposed to view, but happily the tumor had not formed a dense attachment to them. The phrenic nerve was not seen during the operation. There was not much hemorrhage at any time, every wounded vessel being at once controlled with forcipressure forceps. The parts around were carefully examined for more signs of the disease, and it was found to have been freely removed. All bleeding having been stopped, and the wound cavity thoroughly dried, the edges of the incisions were sutured with silkworm gut, and a drainage-tube was inserted at the sternal end of the wound. The wound was dressed with cyanide gauze and salicylic absorbent wool. The patient bore the operation, which lasted one hour and forty minutes, remarkably well.

On January 28th the wound was quite healed, and by February 2d the patient was quite well and anxious to begin work. He had no difficulty in moving his arm in any direction, and there was no sign of any return of the growth, either in the wound or in the neighboring structures.

The growth when cut across was seen to be distinctly growing beneath the periosteum. It was somewhat dense in structure and yellowish white in color.

The specimen was kindly examined microscopically by Dr. H. D. Rolleston, pathologist to the museum at St. George's Hospital, London, and pronounced by him to be a small spindle-celled sarcoma; it was not very vascular, but there was some extravasation of blood into its substance. The specimen is now in the museum of St. George's Hospital, London.

I have thought this case worthy of record, as it is one of the rarest operations in surgery, and one beset with difficulties, causing grave anxiety to the surgeon owing to the close proximity of many vital structures, and it is fraught with peril to the patient. I was led to advise the performance of such an extreme measure for the following reasons, which I laid clearly before the patient, before operating: He was a young man and otherwise healthy and well able to bear the necessary shock of the operation; the growth would inevitably spread and terminate his existence before long; the skin was not implicated in the growth nor were the big veins at the root of the neck pressed upon. That the movements of the upper extremity were perfectly free, and this fact would help me somewhat during the steps of the operation.

I have been at great pains to look up the literature of the subject, and I find that so far only twenty-eight cases have been recorded in which this operation has been done. I have found several where the clavicle has been removed for necrosis, and where the bone was regenerated from the periosteum left behind.

There are also eight instances recorded by Jaeffreson, of Newcastle-on-Tyne, where the clavicle has been removed with the arm and scapula for malignant disease of the shoulder (vide *The Lancet*, vol. i., 1874, p. 759). I must also mention the case recorded by Schneider in the *Archiv. für Klinische Chirurgie*, vol. xxiii., 1887, of penetrating gun-shot wound of the chest, gangrene of a greater part of the left lung supervening, resection of several ribs and left clavicle, and the patient recovered. But the appended list contains only cases where ablation of the clavicle has been performed for malignant disease.

One is struck, on examining the cases that recovered the immediate effects of the operation, how little impairment there is in the movements of the arm. In my own case the movements were perfect, and being a well-drilled man, he took care that his right shoulder should never droop, so that when clothed no one could notice any difference in the two shoulders. This was probably due to the fact that, the outer third of the clavicle being left behind, the clavicular attachments of the trapezius and deltoid muscles were not interfered with. In Mr. Travers's case the patient was able to row on the Thames a few months after the operation. Dr. Britton's patient was able to work as well as ever after the operation. In M. Polaillon's case, where the outer three fourths of the bone were removed, all the movements of the arm were preserved. In Mr. Bowreman Jessett's case, that of a young lady, she was able to do her hair in a very short time after the operation, and in this case the whole clavicle was removed.

The first case ever operated on, that of Dr. Mott, of New York, is of great interest. The patient was nineteen years of age, and lived fifty-four years after the operation. The bone was removed in two pieces, and the tumor was the size of a man's two fists; the operation lasted four hours. The autopsy was made by Dr. F. R. Porcher, and recorded by him in the *American Journal of the Medical Sciences*, vol. lxxxv., pp. 146–148.

I was present when Mr. Rouse removed the whole of the right clavicle from a man aged twenty-nine, in St. George's Hospital, London. The operation lasted two hours, and the subclavian vein, which was lying in contact with the growth, was nicked twice, the wounds being caught up and tied with catgut. Death took place ten days later from septicæmia. In my own case I am convinced as to the value of the scissors in performing such operations, and the ease with which bleeding can be immediately controlled is of great assistance to the surgeon. When I last heard from my patient he was doing well, and as there are instances on record of complete recovery after this operation, a similar result can be hoped for in his case.

22 HARLEY STREET.

The Conclusions of the Astronomer are that the moon is an absolutely sterile planet, a fact which should secure for it a particularly happy attitude on the part of surgeons. In that not impossible future when man has mastered all the forces of nature and harnessed them to his use, we may look to have all major operations done on the moon, where asepsis is normal and absolute.

SAN ANTONIO AND SOUTHWEST TEXAS AS A WINTER RESORT.

By EUGENE M. LITTLEJOHN, M.D.,

THOMASVILLE, N. C.

In a recent issue of the MEDICAL RECORD I attempted to set forth the advantages of the Rocky Mountain region for consumptives, from my own experience as patient and physician. In this article I made only slight reference to that class of patients, who for different reasons are not likely to be benefited by high altitudes. Since this was written (nearly a year ago) I have become a member of this class myself, on account of a kidney complication which necessitated a change to a lower altitude. Besides these cases that are not suited to a high altitude at any time, there is a large number who at this season of the year prefer going to some mild climate, provided it has at the same time a dry, bracing, and tonic atmosphere. I wish now to call attention to a section of country that, in my opinion, is not only the most desirable place for this class of patients, but, as I have had opportunity to learn, is also one of the most favorable climates for lung troubles generally, especially when they are of the catarrhal variety. The section I refer to is San Antonio and Southwest Texas.

In the description of this place it will be seen that outside of its advantages as a residence for lung patients, it is really unsurpassed as a winter home for anyone who can appreciate genial sunshine and invigorating air, of such dryness and purity that it prevents the enervating effect which is produced by other warm Southern climates, where there is so much more humidity in the air. This climate is also conceded to be especially beneficial in winter to chronic catarrhal affections generally, kidney diseases, chronic rheumatism, and many nervous affections which require outdoor exercise and a mild climate in their treatment. While this section of country has come into great prominence in the last few years as a winter resort and a resort for consumptives, yet there are many who have a false idea as to some of the features of this climate. They have heard of the Texas northers, and are afraid to enter the State in winter on this account. In reality, these northers may be pretty cold when they enter the State from the north, but when they reach the neighborhood of San Antonio they are so thinned down and subdued that they cause little trouble, and the air is very dry and stimulating. Besides, they are only periodical, and at other times in winter the prevailing winds are from the southeast principally, which, of course, coming from the Gulf as they do, are mild and pure, and, at this distance inland, are practically free from moisture. These winds I consider a great blessing, as they prevent stagnation of air in the towns and take off all impurities as fast as produced, replacing this with pure, fresh air. These winds are not of great velocity and, as stated before, are not usually cold. San Antonio, which is the principal city of this district, has an altitude of about seven hundred feet, and is situated in an undulating country of varying degrees of altitude which gradually slopes to the Gulf.

There are no marshes or bayous, and the streams are swift running. The Signal Service reports show that at this point, for a series of years, the average number of days during any portion of which the thermometer goes below the freezing-point is fourteen, or about two weeks during the whole winter. Roses are in bloom until Christmas. The number of clear and fair days at San Antonio averages 287. One important advantage that this place has, as a winter resort, is its accessibility. For instance the journey from St. Louis or Memphis can be made without change of cars over the Iron Mountain route and International & Great Northern Railroad direct to San Antonio; there being no high snow-covered mountain passes to contend with, such as the invalid dreads in reaching some of the extreme Western resorts in winter. Another advantage of this place is that both the invalid and pleasure-seeker can find here an amount of diversion not to be found at other winter resorts. San Antonio, which was the old capital of Texas, is a city full of historic associations, and many of the old landmarks, such as the Alamo, are still standing to remind one of the brave deeds of Crockett, Travis, and the other Texan heroes. There is no end to the amusement and diversion to be obtained by watching the customs and gayeties of the Spanish population and half-breeds, which are seen here in perfection. But besides this native and large American population at San Antonio, the city and its excellent hotels are now crowded in winter with wealthy and cultured visitors from all parts of the country. Not only invalids but pleasure-seekers, and those that are there to escape the cold Northern winters. I have spoken here of San Antonio as the principal city of this section, but there are many smaller towns in the vicinity that will suit those who prefer village life. If a higher altitude is desired, those to the northward will be found considerably higher. Boerne, Comfort, Kerrville, Castroville, Bandera, Mason, Fredericksburg, and Llano are all good points; and again, if anyone wishes to rough it on a cattle-ranch or farm, he will find no trouble in getting located suitably near any of these points desired. I will close this with the following extract, quoted from an article read before the American Climatological Association by Dr. M. K. Taylor, Major and Surgeon U. S. Army, retired, who has had a large experience in this country.

"The opinions which have been presented are the result of a pretty large experience in the various sections of the United States. Born, raised, and educated in the North, and with professional and personal experience on the Ocean and Gulf seaboards, and some experience in climbing the Colorado mountains, I think that I speak advisedly when I say, of them all I prefer that Southwestern country where the most comfort can be had for the least trouble and expense. The social relations are excellent, business is thriving, and for those who wish to take their families with them and have their children continue to pursue their studies, the schools of San Antonio afford excellent advantages. For delicate children who require the invigorating influences of moderately cool weather and active out-door life, that climate is all one could wish during the winter season, while spring with its multitude of flowers, its fragrant breezes, its genial sunlight and its evenings, with their soft sweet repose give one a better idea of an earthly paradise than any place we have ever seen or hope to see in this broad land."

October 1, 1892.

Shortening the Round Ligaments.—Dr. Chalot, of Toulouse, employs a modification of Alexander's method of shortening the round ligaments of the uterus in cases of painful retroflexion. He opens up nearly the whole of the inguinal canal, which enables him to reach the entire thickness of the round ligament even in stout subjects; each ligament is then dissected up to the internal ring, or even into the peritoneal cavity. The replacement of the uterus is not obtained by the support of an assistant, but by direct traction on the two ligaments, each of which is then stitched to the walls of the canal along its entire length. No pessary is used after the operation. The results of this method have given Dr. Chalot great satisfaction.—*The Lancet.*

A Rather Dubious Tale.—An item is passing around among our contemporaries to the effect that an epidemic of typhoid fever having broken out in Geneva the sanitary authorities traced it to a particular milk supply, and it was found that the owner of the farm from which the milk came had sent it out in cans which had been cleansed with water from a stream in which the linen of a person suffering from typhoid fever had been washed. The story further goes that the milkman sued the dairyman for damages, and that the Court awarded him $300.

Clinical Department.

A NEUROSIS (?).

By JOHN T. GIBBONS, M.D.,
BROOKLYN, N. Y.

Perhaps the following case may be of some interest to the readers of the Medical Record. It certainly will be to anyone having had a similar one.

Male, aged three, German parentage. Family history tubercular on the maternal side; no previous illness except a diarrhœa due to indiscreet feeding, the remains of which were present at the time the mother brought the child for treatment.

Some days previous the child had fallen in such a manner as to injure the scrotum. Physical examination revealed an enlarged scrotum with an abrasion on the left side. The testicles were normal, and nothing apparent around the genitals to account for the changes that followed. There was a phimosis existing with an œdematous penis, and a hernia on the left side (inguinal) just about perceptible.

The first day, the right leg was swollen to an enormous size, from Poupart's ligament to the tarsus. Extending over the buttocks and down the inner aspects of both limbs was an extensive macular eruption, varying in size from three lines to twenty lines in diameter, and of a very irregular marginal outline. The temperature was 99.2° F.; pulse, 134. The urine contained no albumin but urates in abundance, which deposited rapidly on cooling.

The second day the left leg became swollen during the night, and likewise the right arm from the shoulder-joint to the phalanges. The eruption followed on the arm, though not so extensive, and the change in color took place more rapidly than that on the lower limbs, fading from bright red, purple, purplish yellow, yellow brown, and finally disappearing.

The third day the abdomen was markedly tympanitic, the child apathetic, and taking no notice of surroundings. Pulse, 172; temperature subnormal, 97.4° F. The treatment up to the present had been symptomatic. To stimulate the heart's action the child was placed on

℞. Pulv. moschi .... .01
Pulv. Camphoræ .... .03
Pulv. Opii .... .005
M. Ft. talis dosis No. vi., et Sig.: One powder every hour.

After the fourth powder the child rallied remarkably, the pulse was 112, temperature normal. The tympanites diminished somewhat, and general improvement was manifested.

At 9.30 P.M. I was called again, the mother stating she was afraid the child would "blow up." On arrival, the sight I beheld was remarkable. The abdomen was distended to the utmost. The bowels had not moved for eighteen hours, and the last fæces were of greenish character. He was given the following:

℞. Hydrarg. c. cretæ .... .06
Resorcini .... .04
Pil. sacch. anisi .... q. s.
M. Ft. ch. No. v.; talis dosis et Sig.: One powder every hour as directed.

The tympanites diminished considerably, but not wholly up to present date (October 6th). The pulse was 128; respirations during the last exacerbation raised for the first time to 30, and returned to 22 within a few hours. Temperature 100.2 F.

The fourth day everything was apparently favorable. Pulse, 112; no fever; child takes nourishment of liquid peptonoids and milk.

The fifth day no change from the previous one.

The sixth day, during the night, the right parietal area swelled up, and with it the left eye, the lid of which looked as if it was one enormous bleb. The anæmia was now great, and eyes presented a sunken appearance. He was placed on small doses of arsenic, citrate of iron, and quinine.

The seventh day there was improvement in every direction, swelling disappeared over the boss, and considerably over the eye. The œdema at no time pitted on pressure. After a few hours' play in the morning, the child rested for the day.

The eighth day the child was apparently well out of danger. He continued to improve daily. There was a second eruption similar to the first, but not so extensive in area or character. This disappeared as the first. There were no further points of interest in the case, which is still under observation. With the valuable suggestions of my colleague, Dr. F. Weisbrod, symptomatic treatment, and the kindness of nature, the child is alive to-day. This is the nineteenth day.

Was it a case of Starr's neurosis?

349 Evergreen Avenue.

AN INFANT BORN WITH TEETH.

By J. KAUFMAN, M.D.,
BROOKLYN, N. Y.

The following curious case of an infant born at the seventh month of pregnancy with a full set of teeth I think worthy to be recorded:

On the 27th of this month I delivered Mrs. M. B—— (a primipara, aged seventeen, strong and robust) in her seventh month of pregnancy, of a male child. The labor was rather tedious, and the child was born asphyxiated. On introducing my finger into the child's mouth a sensation of teeth was imparted to it from the upper and lower jaw. I did not pay much attention to this at the time, being occupied with the resuscitation of the child, in which I succeeded. The next day, finding that the child refused to take the breast, I examined its mouth and to my utter astonishment found a full set of teeth in the upper and lower maxillæ. The mother, on being told of this, remarked that she had dreamed it the night before.

HORSE-SHOE KIDNEY.

Dr. George A. Cook, of Miller's Falls, Mass., writes: "In the Medical Record for this week it is reported that Dr. J. S. Thacher exhibited before the New York Pathological Society a horse-shoe kidney. While dissecting at the Long Island College Hospital, Brooklyn, in the winter of 1888 I found in my last 'part' a perfect horse-shoe kidney, the upper portion of the kidneys being united. Each organ had its ureter, artery, and veins. The specimen is in the Hoagland Laboratory, Brooklyn. The subject was a male, thirty-five years of age, who had died of tuberculosis. Most of the arteries within the thorax and abdomen were atheromatous. I send this imperfect description of the specimen on account of the rarity of the condition."

DUDLEY'S OPERATION ON THE CERVIX, WITH A REPORT OF FIVE CASES.

By T. D. MARION, M.D.,
CHESTER, S.C.

In the *American Journal of Obstetrics* for February, 1891, Dr. E. C. Dudley, of Chicago, recommends "A Plastic Operation Designed to Straighten the Antiflexed Uterus," modestly suggesting its adoption "when the indication to be fulfilled is wholly or in part mechanical." Soon after reading this article I determined to perform the operation on two cases that had given me no little trouble. Dilatation with steel instruments and the introduction of drainage-plugs would give relief to the dysmenorrhœa, and symptoms incident thereto for two or three months; but, as on many previous occasions, the old symptoms would return, which were alike annoying to myself and patients.

In this connection I will be pardoned, I trust, for re-

calling the experience of a very prominent gynecologist of New York City, as expressed by him a few years ago, to which he obtained much better results in the treatment of anteflexion than in retro-displacements, claiming that free dilatations, judiciously executed, would accomplish alleviation of the patient's subjective symptoms. The idea seemed quite plausible, and coming from one of the masters I was eager to put the views of this specialist in practice. But the necessity for a more radical method of dealing with this trouble becomes more apparent and convincing the more so-called free dilatations are practiced. At best, in the vast majority of cases, the procedure is but temporary in its effects, and he who pins his faith to it as a curative agent is doomed to disappointment. The following cases are briefly submitted in support of Dudley's operation.

Case I.—Mrs. T. A. S——, aged twenty-nine, married ten years. Menstruation was always painful, which gradually became more intense after her marriage. The week before and during the flow, complained of severe cramping in stomach as well as in the bowels, headache, backache, palpitation, loss of appetite, etc. At first anodynes and tonics, in short, the batteries of the materia medica were discharged on her, but, it is needless to say, with negative results. A few years later a doctor, recently in attendance at one of the Post-graduate schools, saw at once that the thing to do was free dilatations, all of which gave relief for a time, but both doctor and patient became tired and discouraged over repeated failures to obtain permanent benefit, and in consequence the patient drifted back to the old habit of taking anodynes. That she escaped septic infection, with the tubes and ovaries undisturbed, must be a great comfort to all the parties concerned. Free mobility of the uterus excluded the possibility of tubal complications, and made the way clear to proceed with the operation of dividing the cervix well back to, but not beyond, the vaginal junction, as Dr. Dudley is wont to do. "The sutures are not introduced in such a manner as to stitch the intracervical to the vaginal margin of the cut surface, but the cut surface is folded upon itself in a direction at right angles to this, *i.e.*, on either side of that point at the margin of the os externum where the backward incision commenced, and is stitched to the very angle of the incision, so that the cut surface is folded upon itself, not from within outward, but from before backward." This done the cervix no longer lies parallel with the fundus, but projects back toward the concavity of the sacrum—as was demonstrated in the case before me. The operation relieved the patient of all the old torture she endured periodically for years. Six months after the operation pregnancy followed, over the occurrence of which she was highly satisfied.

Case II.—Mrs. S. P——, aged twenty-eight, married seven years. Sterile; marked anteflexion; menstruation exceedingly painful for several years, for which she had been dilated with steel instruments time and again, while under the influence of chloroform, but the good results obtained would always prove temporary.

For two years previous to consulting me she had been having convulsions, commencing the day before, and recurring at intervals of two or three hours until the flow was established. The cervix was elongated and almost of cartilaginous hardness. After a preparatory course of hot-water injections and medicated tampons (glycerine and baro-glyceride), the cervix was divided and treated as before. It is now twelve months since the operation, and during this time she has been free from pain and convulsions. She has also gained thirty-eight pounds in weight.

Case III.—Mrs. J. B——, aged thirty-two. Dysmenorrhœa from girlhood. Sterile. The mechanical indications were much the same as in the two preceding cases. Frequent and painful urination prevented sleep, which added greatly to her general discomfort. The appetite was gone, and nausea almost constant. Bowels costive for two or three days, when a "milky" diarrhœa would set in and last three or four days, which no amount of medication on the part of her physician was able to overcome. She had a profuse leucorrhœa when brought to me from an adjoining county by her physician, who, be it said to his credit, was not a gynecologist. The cervix was elongated and eroded, the fundus resting on the bladder, there was also some fulness on the left side of the uterus, with partial fixation, which was reckoned as the danger-signal against operation. Whether this fulness was due to enlargement of the pampiniform plexus, or to a mild salpingitis, I am unable to say. The risk of operative interference in the face of peri-uterine complications was explained to my patient, and her co-operation was readily obtained in carrying out the necessary preliminaries, which consisted in hot-water injections (medicated with boracic acid) and baro-glyceride tampons to the lateral cul-de-sac. After persevering eight weeks with this local treatment, free mobility of the uterus was obtained, when the cervix was cut back freely as before, and with three sutures in each flap the bleeding surfaces were doubled over on to themselves. It is now nine months since the operation, and she has had no return of her old symptoms, for which she is very profuse in her expressions of gratitude. Twice has she failed to menstruate, and this, coupled with other evidence, makes pregnancy almost an assured fact.

Case IV.—Miss ——, twenty-one years of age, a resident of Florida, had been on a protracted visit to a famous health resort in North Carolina, and on her return home stopped with a friend in an adjoining county, who happened to be a former patient of mine, to whom she related her sufferings, and also her intention of going to a hospital in Atlanta, Ga., and placing herself under the special care of a gynecologist. She had failed to obtain any benefit from her stay in the mountains, and, altogether, was a much discouraged woman—was exceedingly nervous and hysterical, at times craving to die rather than live. She warned me that if I even touched her over the bowels it would bring on a convulsion. Preferring to take her word for it, chloroform was given, and a digital examination satisfied me that Dudley's operation, properly done, would cure her. The dysmenorrhœa dated back to her first menstruation. During the eighteen months previous to operation, metrorrhagia existed as a complication. The vegetations causing it were removed by Sims's smallest curette, the cavity swabbed with a bichloride solution (1 to 1,000) and followed by packings of iodoform gauze, which Polk, of New York, has done so much to make popular in this special field. The packings were allowed to remain undisturbed for three days, when they were removed and Dudley's operation performed. This was followed by the most happy results. Nearly a year has elapsed since the operation, and during this time there has been no return of the dysmenorrhœa, headache, neurasthenia, etc. As is often the case after using the curette for fungous granulations, she failed to menstruate on two succeeding occasions.

Case V.—This case was in many respects similar to Case IV. The anteflexion probably being more acute. She has menstruated once since the operation, which was free from pain.

In conclusion I will say, that in four of the cases operated on, the anterior lip was not removed as advocated by Dudley. In not one of the cases did the ovaries and tubes react on the treatment; they had been well prepared. Perfect cleanliness and scrupulous attention to antiseptic details must be regarded as indispensable requisites to success.

A Patent Medicine of Some Utility.—A Dublin newspaper recently contained the following advertisement: "Wanted, a gentleman to undertake the sale of a patent medicine. The advertiser guarantees that it will be profitable to the undertaker." Such a guarantee for many a patent medicine would be very profitable to the public.

THROMBOSIS OF THE PULMONARY ARTERY IN THE PUERPERAL STATE.[1]

By W. W. HEWLETT, M.D.,

BABYLON, LONG ISLAND.

On June 24, 1892, I attended Mrs. H——, a strong, healthy woman, in her sixth confinement. The labor was perfectly normal. She assured me that she had never had any trouble in childbirth. Contrary to my advice she sat up on the fourth day, declaring that she had always sat up as early as that after previous labors.

The lochia was normal, the lacteal secretion abundant, and everything went on smoothly until the twelfth day, when, while in the sitting position, she was suddenly seized with the most intense dyspnœa, extreme restlessness, followed by cold extremities, cyanosis, nausea, and profound weakness.

Owing to my absence, Dr. A. B. Leggett was hastily summoned. He promptly gave her ammonia and whiskey, and applied bottles of hot water to her feet. I saw her four hours after, when her respirations were 58, pulse 130, and very feeble, temperature normal. She was calling for air, had profuse perspiration, cold extremities, nails of a livid color, and her facial expression indicated great prostration. There was no pain; intellect perfectly clear. Her only complaints were of shortness of breath and extreme cold.

My first suspicion was that hemorrhage had taken place, but a vaginal examination soon settled that theory in the negative. After two hypodermic injections of whiskey, a half hour apart, she revived a little; but every effort to raise herself or even to turn in bed was followed immediately by an exaggeration of all the symptoms.

I explained to her the importance of maintaining the most absolute rest in the recumbent position, keeping the extremities warm, free stimulation with whiskey and ammonia, the use of digitalis, and emptying the bladder as often as required.

For a week or more the patient suffered from faintness, difficulty of breathing, and cold sensations. Auscultation revealed nothing abnormal, though it was quite impossible to examine the chest posteriorly. Heart action was feeble and tumultuous. At times the respirations were as high as 80, her suffering from dyspnœa was painful to witness, and death seemed near at hand.

After the eighth day improvement began, but it was very gradual. She was not able to sit in her chair until the beginning of the third week—about five weeks from the day of confinement. After that day improvement was uninterrupted, and recovery was complete by September 1st.

Such, in brief, is the history of a disease of which we find little or no mention in the works of the older writers. A case presenting such an array of symptoms would have been called "syncope."

The importance of possessing a knowledge of this disease may be inferred from the statement by Lusk that "thrombosis of the veins furnishes the most frequent cause of sudden death in labor and during the puerperal period."

Causes.—According to Lusk and Barker it may occur spontaneously, from a condition of the blood hyperinosis. Dr. E. L. Partridge, of New York, reported a case in the MEDICAL RECORD, of February 27, 1892. In that case nothing abnormal occurred until the tenth day, when, owing to a slight odor to the lochia, a vaginal douche was given, which was immediately followed by hemorrhage and the constant and excited complaint from the patient that she was very sick. Cyanosis ensued, followed by cold extremities, rapid pulse, violent dyspnœa, and death in about three hours.

In this case there were a number of clots of a dark color discharged. In commenting upon it, the reporter says: "The mechanical disturbance of the uterus by the forcible dislodgement of such clots, which had resisted spontaneous discharge for days, could materially assist in freeing some coagulum situated in a uterine vessel and facilitate its movement through the uterine vein into the ascending vena cava."

Spiegelberg states that "the emboli, which become detached during or shortly after labor, proceed from clots formed at the site of the placenta. Usually there is at first hemorrhage from partial detachment of the placenta, then thrombus formation in the veins, the clots, in the absence of uterine retraction, extending from the open mouths of the sinuses in the direction of the heart; and, finally, under a powerful contraction . . . the clot is set adrift from its moorings, and is washed upward through the vena cava to the right side of the heart, and thence to the branches of the pulmonary artery." It is hardly within the scope of this paper to consider further the symptomatology of this affection. It is difficult to discriminate between embolism and thrombosis. In fact, from a clinical point of view, it is not essential.

In the diagnosis care should be taken not to confound it with syncope, or shock, or post-partum hemorrhage. In thrombosis and embolism there is asphyxia, clear intellect, and intense dyspnœa added to the other conditions present in syncope, viz., rapid pulse, pallor, and low temperature.

In syncope the dyspnœa is not present, and the patient loses consciousness. If the symptoms are due to hemorrhage a vaginal examination will soon determine that point.

Treatment.—We should endeavor to support the flagging heart, which will relieve the dyspnœa, have the patient keep as quiet as possible, in the most comfortable position, avoid every possible source of excitement, and sustain the powers of life by proper food, stimulants, and tonics. If the stomach is too weak to absorb, give your patient brandy and digitalis subcutaneously; apply heat to the extremities, and empty the bladder in the catheter if necessary. Digitalis and ammonia should be continued until dyspnœa and excessive heart action have entirely subsided. Quinine in tonic doses should be given, and also alcoholic stimulants, according to general indications.

Great urgency of symptoms should not lead us to despair, for the most unpromising case may end in recovery, and much can be accomplished by prompt and judicious treatment.

A CASE OF DERMATITIS EXFOLIATIVA.

By WHITMORE STEELE, M.D.,

ASSISTANT PHYSICIAN, UTICA STATE HOSPITAL,

UTICA, N. Y.

That there is a close resemblance between pityriasis rubra, psoriasis, general eczema, recurrent erythema, pemphigus foliaceus, and dermatitis exfoliativa, is remarked by all dermatologists. Indeed, some make no distinction between the chronic form of pityriasis rubra and this form of dermatitis. Fox[1] describes it as a rare form of skin disease, characterized by severity of constitutional symptoms, and giving, as a rule, a bad prognosis. Duhring[2] describes it under the general heading of pityriasis rubra, as a rare form of skin disease, and one easily confounded with other more common forms of inflammation.

Brocq, as quoted by Van Harlingen in the "Reference Handbook of the Medical Sciences," after a careful analysis of a number of cases of the above-mentioned analogous affections, considers it to be a distinct entity, and entitled to separate consideration.

The case which I have to report corresponds in all points to the symptoms noted in the descriptions of Fox, Duhring, Brocq, and Van Harlingen. Mrs. M——, a patient at the Utica State Hospital, convalescing from an attack of melancholia, came under my care three weeks ago, suffering with a dermatitis of considerable extent.

[1] Atlas of Skin Diseases. [2] Diseases of the Skin.

She gave the history of having had her first attack about ten years ago, at which time she was living the life of a farmer's wife, was considerably exposed to the inclemencies of the weather, and was not at all careful in protecting herself therefrom. She describes this, her first attack, as being characterized by a reddish eruption over the entire body, some swelling of the extremities, and an intense burning and itching, made worse by exposure or by becoming overheated. This lasted for a number of months, into the summer, when exposure to the sun's rays increased the inflammation very much. The redness and swelling lasted several weeks, whereupon a very extensive exfoliation of the epidermis took place; she also lost her finger- and toe-nails and a considerable amount of her hair at this time. She recovered from this attack, but had several recurrences, not as severe in degree, up to the time of her admission to this hospital, which was over one and a half year ago.

One month after her admission, she was taken with a very severe attack of the same trouble, this time characterized by marked swelling of the extremities and of the face, a reddish papular eruption, accompanied by marked prostration, febrile disturbance, and quite severe gastric symptoms. It was diagnosed at this time as erysipelas, and treated accordingly. At the end of two weeks the swelling and eruption diminished, and very extensive exfoliation took place; the patient also described a very offensive exudation coming from the skin. Her toe-nails and finger-nails came off, and her hair fell out to a great extent. At this time she commenced to be troubled with an ulcer in the right nostril, which has continued slowly spreading through the nasal septum, so that now there is a cavity connecting the two nostrils, from which there is a foul discharge, which is increased in quantity during the recurrence of these attacks of dermatitis. After the cessation of this severe attack, which lasted about three months, her general condition was very poor, appetite gone, very emaciated, and anæmic.

Since this time, and up to the present date, she has had three or four attacks, most of them mild and of short duration. Her present attack commenced about three weeks ago, at which time, for several days, her skin was very dry and burned considerably. This state was followed by a reddish papular eruption, and some œdema of the feet and hands. The eruption disappeared on pressure, leaving a yellowish spot marking the pressure, the redness returning slowly. The papules were from one-eighth to one-fourth of an inch in diameter, and were found more abundantly on the extensor surfaces of the arms and forearms, and over the external aspect of the thighs—also were very abundant over the back. The swelling and eruption began to diminish in about one week, and for one week past the patient has been very extensively desquamating, her hair also has fallen out to a considerable extent. At present she complains more of the itching, which is intense, and also of some stiffness at the joints. The entire body is covered with fine scales which brush off very easily, the exfoliation is more marked at the knee and elbow joints. There has been marked malaise, and at present her blood is in very poor condition, showing only fifty-five per cent. of hæmoglobin and 2,500,000 red cells. She improved considerably under alkaline washes daily, and thirty-grain doses of potassium acetate three times daily. In consideration of the previous history of this case, and the symptoms observed while under treatment in this hospital, I cannot but think the case is suitable for classification under the heading of Dermatitis Exfoliativa.

The Indian Medical Service.—There is much bitter complaint of unfair treatment of officers of the East Indian Medical Service, and an agitation has been started for the abolition of the service and the assumption of the duties of its officers by the members of the Army Medical Staff.

Progress of Medical Science.

Abdominal Pressure for Constipation.—Dr. Feilcherfeld recommends the application of steady pressure upon the walls of the abdomen in cases of obstinate constipation. He for this purpose employs cushions containing three or four pounds of shot, so applied by means of layers of lint that they exert an equable pressure all over the abdomen. Generally the application for an hour, or an hour and a half, suffices to produce a good stool. The remedy can be used at night on going to bed or in the morning before rising. This remedy Dr. Feilchenfeld has found particularly useful in cases where there were hæmorrhoids.—*Provincial Medical Journal.*

The Insanity of Egotism.—An article has appeared in the *North American Review*, entitled "A Modern Form of Insanity," by Dr. H. S. Williams, which throws some interesting light upon those indifferently understood persons "the cranks." Dr. Williams holds that the great majority of these unfortunates are diseased mentally. The disease has been termed "paranoia," and more than any other insanity is the result of an inherited mental instability. The progenitors may not have been insane, but they may have been nervously unstable from drunkenness or from some wasting disease. The offspring may be merely nervous; he may have epilepsy or chorea; he may be insane. At the best, he may usually, if properly educated, learn to understand himself and to live a sane and useful life. We have here to do, however, only with the cases in which a wrong environing influence aids in the development of a particular form of insanity. It is possible to outline pretty definitely the mental attributes. One may even point out in the child what might be termed the paranoiac temperament. Its characteristics are morbid sensitiveness and great egotism. Unfortunately, the parents of such a child usually take pride in the egotism that leads to eccentric acts, while the extreme precocity of many of these subjects causes their egotism to be fostered by ill-adjudged praise. Usually the child of paranoiac temperament is the genius of his family and the show pupil at school. Pampered and praised, even though the entire household becomes subordinated to his sovereign will, he is not satisfied, believing that he does not receive his dues. With that idea, the germs of paranoia are implanted in his mind. Whether or not these germs will develop into the pathological condition that we are discussing, will depend largely upon the influences that are brought to bear upon them during adolescence and early manhood. Perhaps the most unfavorable environment is one in which the mind is developed at the expense of the body. And of course, the brilliant child is the one whose mental training will be forced. The other children of the family may stay at home, but this one must be sent to college and fitted for one of the learned professions. Usually he seems to justify this discrimination. Often he is an "honor" man at college, and he starts out into the world with every seeming prospect of an eminently prosperous career. But all this time he has become more and more eccentric. He has associated little with his fellows. Often he has shown himself possessed of extraordinary energy and capacity for application. A peculiarity often noted is a tendency to make elaborate written records of trivial subjects. Occasionally the young person of paranoiac temperament breaks down under the unbalancing influences of overstudy while still at school. But usually the critical stress comes after he has gone out into the world. He is usually not yet insane. He may never become so. If his business or professional ventures succeed, he may become distinguished, and contact with the world may gradually correct the morbid tendencies. But if adverse circumstances arise and refuse to be put down, especially if the individual's vanity is wounded by failure to rise to the heights pictured by ambition, morbid brooding may develop out of vanity, selfishness, and suspicion, the delu-

sion of persecution. But it must not be supposed that the mature condition is merely egotism and egoism run riot. That it has come to be something more than this is proved by the appearance, sooner or later, of hallucinations of one or more of the senses. These do not necessarily coincide at first with delusions. The incipient paranoiac may hear voices about him and for a time be able to convince himself of their unreality. But, sooner or later, these sounds become so tangible that they have the full force and import of actual voices. At first he hears them only when people are actually speaking, his mind merely misinterpreting what it hears. This perversion is technically termed an illusion. But at last he hears words and sentences when no real sound comes to his ears; these are true hallucinations. Perversions of other senses usually precede or follow this one. Illusions of touch and smell are common. The former lead to a belief in invisible spirits that touch the body; and the latter convince the patient that attempts are being made to poison him with noxious gases. When to this cluster of perverted sensations hallucinations of sight are added, the galaxy is complete, and the victim moves and has his being in an ideal world peopled with odors, tastes, sounds, and sights that are shut out from the common herd. The patient lives a dual existence. For a time he is able to treat the actual world in the old familiar way—that is, sanely; meanwhile keeping the new and strange world hidden. But gradually he comes to confound the two existences. He comes to believe that hosts of people are leagued against him, and all sane interests give way to a desire to thwart those imagined foes. At this stage of his morbid career the patient becomes very dangerous, though he may still seem to be the most peaceable of men. Murders are often committed by patients in this condition. But many more intended murders that are carefully planned are never executed because of the irresolution of the would-be murderer.—*The Journal of the American Medical Association.*

Phenacetin in Vesical Irritation.—Dr. Traill Green recommends the employment of phenacetin for the relief of frequent micturition and vesical irritation in the aged.

Hereditary Ataxia.—Dr. Loogard has placed on record three cases of hereditary ataxia in children of one family, which came under his observation. The hereditary origin of the disease was unmistakable, without any cause being discoverable in either the parents or the relatives. In none of them was a deficient development to be found. The disease had appeared acutely in the eighth to the fourteenth year, and without any apparent cause. It began with a light feverish symptom and very little pain, to rapidly pass over into the progressive chronic form. Ataxia is the most prominent symptom. Two of the patients pass the day in a chair, the other crawls about still, dragging himself around like a drunken man. Besides the ordinary spinal ataxia, with impossibility of reckoning the force and measure of movement, there is also an inclination to the cerebellar form, there being an absolute loss of equilibrium in the two oldest, the youngest walking in a zigzag manner. But besides these two peculiarities of movement, and the undoubted spastic gait, in at rest the tonus of the muscles is good and even somewhat increased. This is explained by implication of the pyramidal paths. The opposite holds true of tabes dorsalis. In one of the patients, a male, there is a slight inclination to club-foot. The muscular sense, on applying the usual tests, seemed to be better than would be expected. This is especially true in the dorsal position. In the standing position the balance is lost immediately on closing the eyes. As in tabes, the tendon reflex is absent, while the cutaneous reflex is present. It may even be exaggerated. The symptoms are especially pronounced in the upper extremities. Speech is but slightly disturbed in one, and nystagmus is to be seen in none. Hence the condition in question is a slowly progressive process of upward direction. Two of the patients relations are scoliotic. In contrast to the weakness of the lower extremities the gross strength of the muscles was striking, for the resistance offered was quite considerable. Only in one was a weakness of the ilio-psoas muscle to be discovered of both sides. This was also probably true to a less extent of the pelvic muscles, especially of the glutei. All the senses of the patients were good, only one of them presenting a slight limitation of the field of vision. If to these symptoms there be added that the affection ran a painless course, without atrophy and alteration of the electric reaction of the nerves and muscles, that no trophic changes were to be discovered, that the bladder and rectum functionated regularly, then the picture of hereditary ataxia was filled in its chief points.—*Journal of Nervous and Mental Disease.*

The Surgery of the Gall-bladder.—Professor Czerny, of Heidelberg, offers the following conclusions in regard to the surgery of the gall-bladder: 1. Gall-stones require operative interference as soon as they cause frequently repeated and long continued sickness. 2. Empyema of the gall-bladder always calls for an operation; hydrops of it only when it causes trouble. 3. The typical operation for calculi in the gall-bladder consists of the incision, evacuation, and suture of the gall-bladder; with drainage of the abdominal cavity (for a short time). 4. If the ductus cysticus be not pervious and the gall-bladder itself is inflamed, and its contents considerably altered, a temporary biliary fistula should be established. 5. Extirpation of the gall-bladder is only indicated in severe inflammatory or carcinomatous degeneration. 6. In occlusion of the ductus choledochus operation is indicated as long as the strength of the patient will permit. If we do not succeed in removing the obstruction (stone or kinking), then the establishment of a fistula between gall-bladder and duodenum is to be recommended. 7. The best way to reach the gall-bladder is a hook-like incision (⌟) the vertical shank of which lies in the linea alba, and its horizontal shank runs immediately beneath the umbilicus toward the right. (Langenbuch described a ⊢ like incision; but the author thinks that by means of his incision the gall-bladder as well as the ducts can be more rationally investigated.) 8. The risk of life, will, as far as can be seen now, be less than in operations on the urinary bladder.—*The Annals of Surgery.*

Laminectomy for Pott's Paraplegia.—From a study of this subject, published in the *Annals of Surgery* for October, 1892, Dr. S Lloyd reaches the following conclusions: The operation is naturally contra-indicated, 1. In cases where there are other complicating tubercular lesions. 2. In cases where mechanical treatment has not been applied. It is indicated, 1. In cases where posterior spinal disease is made out as the cause of the paraplegia. 2. In cases where the lesion seems to indicate the failure of mechanical treatment, *i.e.*, where dislocation has occurred or where a sequestrum is causing the compression. 3. In cases where during the employment of intelligently applied apparatus the symptoms continue to increase in severity. 4. In cases where, after a certain period of careful mechanical treatment, say eighteen months, the condition has remained stationary. 5. In cases where pressure myelitis threatens the integrity of the cord.

In all cases where sinuses lead down to, or can be safely straightened so as to allow the probe to explore the abscess cavity with which they communicate, they should be enlarged so as to provide thorough drainage, and if sequestra are present they should be removed. The surgeon should incise and treat all abscesses connecting with the spine, approaching near enough to the skin to allow of their being opened without a dangerous dissection; they should be then explored, washed out, and drained. Although the statistics of the cervical cases are slightly less favorable than those of the other regions, the dangers to life even without operative inter-

ference are also greater. One of the cervical cases died from inhibition of the phrenic nerves. In this case the disease was localized at the third and fourth cervical vertebræ, and in order to determine the presence or absence of an abscess or tumor in the cord, exploratory puncture was resorted to. The result emphasizes the dangers of interference with the cord where the lesion is at the level.

Observations on the Etiology of Malaria.—Dr. Ludwig Kamen has observed the following changes in Laveran's hæmatozoan during malarial chills. In a case of the quartan type, the following observations were made upon the blood—First day: A few small endoglobular parasites having a few peripheral pigment-granules were seen in the red corpuscles. Second day: Endoglobular plasmodia occupying the major part of the corpuscles. Besides these there are cells similar to those of the first day, but more numerous. Third day: Completely developed organisms occupying the entire blood-cell except a narrow peripheral zone. The pigment granules are scattered uniformly throughout the protoplasm. During the chill: The pigment is collected centrally in a round mass, or at times in the form of a minute radial band; marked differentiation of protoplasm. In addition individuals not yet fully developed. During the fever: Division of the parent cell into daughter cells and mature daughter cells, with disintegration of the remaining portion of the older cells. During the sweat: Pigment disks, besides certain misshapen protoplasmic masses, which apparently are dead plasmodia. The new generation does not precede the fever, but the two occur simultaneously. At the end of the vegetative stage the fever appears. The time of apyrexia corresponds to the vegetative period, and that of pyrexia to the proliferation period. Every sporulation means another chill. The time intervening depends upon the time required to pass from one phase to another. In discussing the probability of different organisms giving rise to the various forms of malaria, this division is made: Hæmamamœba malariæ—quartan; hæmamamœba vivax—tertian; hæmamamœba præcox—quotidian; and the pernicious and continued fevers—hæmamamœba immaculata; colorless variety, similar to the foregoing in its pathology; and, lastly, the Laverania malariæ, as the cause of chronic malaria.—*The North American Practitioner.*

Flaming Surgical Wounds.—M. Felizet gave an interesting account of the treatment of several cases of surgical wounds by the flame of the blow-pipe. He said that in many surgical lesions, and tuberculous affections in particular, it was often difficult to draw a positive line between the healthy and the diseased tissue, consequently it is necessary to complete the operation of the knife, the chisel, or the curette by the application of certain caustic solutions, such as chloride of zinc, etc. After the most complete resection there remains always enough of tuberculous matter to infect quite a series of animals when injected. The method he has employed in a great number of cases had for aim to destroy the diseased parts and to provoke a reaction which produces a zone of protection against the invasion of infectious matter. The principle of this method consists in passing rapidly over the wound the flame of a blow-pipe of which the temperature attains 27–32° F. He obtained by this treatment thirty-eight cures with suppuration, fourteen resections of the knee, eight of the hip, five cold abscesses of the same joint, one enormous abscess of the breast, one adenitis, etc. The lips of the wound are protected by several compresses steeped in an antiseptic solution, and the flame of a blow-pipe is passed rapidly over all the raw surface. The reaction is insignificant, and the lips of the wound, which are always left untouched, are brought together over a seared and consequently dried surface. M. Nélaton said that in two cases of cancer he was able to retard a relapse by the use of the gas cautery.—*Medical Press.*

Treatment of Typhoid Fever by Thallin.—Dr. Schmid has recently treated twenty cases, with only two deaths. At the outset calomel was administered, and as soon as the diagnosis was established, sulphate of thallin, in one or two per cent. aqueous solution, was administered every hour from six in the morning until nine at night, and in the night at two or three hour intervals. The initial dose was from one and one-half to three grains. This was increased every second or fourth hour by sixths of a grain until the temperature approached the normal or a little below it. This amount of the remedy was continued for from three to five days, then gradually diminished so long as the temperature remained about the normal. When it became subnormal the drug was omitted until it began to rise. The average duration of the use of this remedy was about seventeen days. Of the two fatal cases, in one the autopsy showed a fatty heart and very large spleen; in the other, a perforation near the ileo-cæcal valve. The author believes that thallin in typhoid fever is of equal value with hydro therapeutic treatment.—*Correspondenz-blatt für Schweizer Aerzte.*

The Increasing Prevalence of Tapeworm.—French physicians have been considerably agitated over the fact that while the population of the country is rapidly decreasing, in consequence of an increased death-rate acting in conjunction with a decrease in the birth-rate, tape-worms are rapidly increasing. There has been considerable discussion as to the source of the tape-worm so commonly met with, especially on the Belgian and Swiss frontiers, and the Mediterranean shore. Berenger Feraud maintains that tape-worm is chiefly derived from beef, while Colin insists that the pig and the cow are equally prolific sources of this parasite. He claims to have discovered, also, that both these animals are infected by some species of cysticercus, so that it is impossible to tell by examination of the worm whether it is derived from the cow or the pig. Colin also calls attention to the great frequency with which cysticerci are to be found in the flesh sold in public markets. If a similar investigation were made in this country, it would doubtless show that tape-worm is increasing in the United States with fully as great rapidity as in France, since there is practically no system of meat inspection in this country capable of protecting, even to a slight degree, more than a very small proportion of the population. The consequence is, that not only is the flesh of animals infected with the embryos of tape-worm frequently eaten, thus establishing the disease in human alimentary canals, but infected persons are going about scattering the eggs of the parasite by the million, infecting water-courses, through sewerage systems, and thus rapidly multiplying the disease in domestic animals which are used for food, so that a vicious circle is formed, by which the disease is bound to increase more and more. This is only one of the grave questions relating to the food-supply, and it should be seriously considered by our legislative sanitary authorities, for it is certainly one which demands attention.—*The Bacteriological World.*

A Quick Method of Distinguishing the Comma Bacillus from Other Micro-Organisms.—It is important that Asiatic cholera should be recognized quickly, so that means for its prevention may be used, and any simple test which will enable a medical man to distinguish between ordinary cholera nostras or summer diarrhœa and the graver Asiatic cholera is of importance. A small quantity of the suspected stools is taken, and a plate cultivation made in the usual way. After twenty-four hours several colonies of bacteria will have developed, and one or more of these colonies is transferred to a tube containing nutritive bouillon containing peptone (ordinary nutritive gelatine will do equally well). The tubes are then placed in the incubator for twelve hours at 30° C., and a culture got which is treated with pure sulphuric acid free from nitrites, when there will appear in the culture a reddish-violet or purplish-red color. This color is not got

with Finkler's, Emmerich's, and other intestinal bacteria usually classed with the true cholera bacilli. Fraënkel says: "Bouillon cultures exhibit the reaction very distinctly after remaining from ten to twelve hours in the incubator, while the gelatine cultures furnish it only after some days, whenever liquefaction has attached the greater part of the culture medium." The explanation of this reaction is, according to Salkowski, that it is the common indol reaction, the indol being formed from the albuminates in the cholera cultures. The nitrates present in the salt and peptone, as also in the gelatine, are reduced by the cholera bacilli, and this affords us a quick method of distinguishing the cholera bacilli from other micro-organisms. The vibrio of Metschnikoff, which is found in the intestinal canal of poultry, also gives this reaction, but its growth on a gelatine plate is altogether different from that of Koch's comma bacillus. On developing these two growths in tubes containing bouillon or sterile soup a marked difference is seen, as the bouillon in which the true cholera bacillus is growing, keeps clear for a long time, and does not change; while the bouillon with the vibrio Metschnikoff becomes grayish-white and very cloudy after a short time.—*The Sanitary Journal.*

Treatment of Insomnia.—Dr. Collins, of New York, contrasts the action of chloralamid and sulfonal in the treatment of insomnia, and arrives at the following conclusions: 1. Chloralamid is a safe, and one of the most reliable, hypnotics 2. It is not ordinarily followed by distressing after-symptoms, particularly headache. 3. It is especially valuable as a hypnotic where pain is a potent factor, but not violent. 4. In cases of insomnia, where there is excessive activity of the brain, it is also useful. 5. On account of its stimulating activity of the respiratory function, it is the hypnotic *par excellence* in nervous exhaustion, associated with an asthenic condition of respiration and symptom complex indirectly dependent upon this, brought about by defective oxidation and the formation of unstaple chemical compounds in the system. 6. On account of its very slight action in depressing the circulation it can be given, in diseases associated with a weak heart, with greater safety than most other hypnotics, not excepting chloral itself. 7. It is conveniently administered in the shape of an elixir, and this overcomes the need of dissolving it. 8. Its dose is from one to three scruples, administered one hour before sleep is desired, and this should not be repeated within two hours, for occasionally the action of the drug is delayed. Sulfonal is preferred when we wish to get very rapid action. It should be given dissolved in boiling water, taken as hot as possible. In this way it is at once absorbed, sleep frequently occurring in from fifteen to twenty minutes. The disadvantages of sulfonal are that the patient is liable to form the sulfonal habit, and that its effects last through part of the following day.—*Journal of Nervous and Mental Disease.*

Resorcin in Ulcer of the Stomach.—Dr. Pope reports sixteen cases of ulcer of the stomach treated satisfactorily with resorcin. He concluded to use it because it was analgesic, antiseptic, and hæmostatic, all these conditions being present in so many of the cases. He gave five-grain doses dissolved in one ounce of water, when the stomach was empty. It stops the pain at once and controls the sensitiveness of the stomach, enabling it to retain food nicely. It has no influence in reflex nervous vomiting. The author insisted upon rest in bed in severe cases, and restricted the diet to milk, predigested in some cases. He did not have to use suppositories or food per rectum, in any case.—*Chicago Medical Times.*

Filtered or Boiled Water?—Martin asserts that many filters, so far from separating the bacteria, may even make the water richer in these organisms. Boiled water has lost its carbonic-acid gas, and the salts of lime and magnesia are precipitated. The taste is flat, although on standing in a cool place it reabsorbs the greater portion of the lost gas. Even boiled water ought not to be long preserved. The problem may be solved by heating the water without loss of air, cooling it mechanically, and adding oxygen by means of an air-pump. It can also be boiled in closed bottles. Investigations have shown that the slight differences observed in the chemical composition of the water before and after sterilization have not altered its potability. With a filter, one can drink only the water of a known source. With boiling, one can use any water. Boiling should be the procedure of choice as soon as any suspicion arises. It should be the rule, especially in large cities, during the progress of any epidemic.—*Gazette Hebdomadaire.*

Rapidly Fatal Leukæmia after Traumatism.—Dr. Greiwe reports the case of a locksmith, twenty-eight years of age, previously in apparently perfect health, who complained of severe pain in the left hypochondrium after having lifted an unusually heavy weight. One day later hemorrhage from the mouth took place, and this was repeated on the following day. The patient had lived amid favorable conditions, and had always had a sufficiency of good food; but he was intensely anæmic, and presented numerous subcutaneous extravasations of blood, which he had observed but had ascribed to injuries received in his work. There was continuous bleeding from the gums. The case was thought to be one of scorbutus. An examination of the blood, however, revealed the existence of lymphatic leukæmia, large lymphocytes predominating. Further examination now showed that the cervical, brachial, inguinal, and axillary lymphatic glands were slightly enlarged and sensitive to pressure. The spleen and liver were also found to be enlarged. Hemorrhage from the nose and mouth was repeated; new subcutaneous extravasations occurred, and the patient died of asthenia on the tenth day after the injury. The findings at the autopsy confirmed the diagnosis of leukæmia. The author holds that the trauma did not act as the cause of the disease, but only served to call into activity a previously latent condition.—*Berliner Klinische Wochenschrift.*

Medical Treatment of Rectal Cancer.—The question of medical treatment of cancer of the rectum, in contradistinction to surgical procedure, is an interesting one, seeing that the latter is of so little promise in many cases, and that a very short immunity only from recurrence is obtained after running the gauntlet of a severe surgical operation. For such cases, where the disease is advanced and the progress slow, M. Dujardin-Beaumetz has devised a plan of treatment of which he reports favorably, and which he credits with being able to prolong the patient's life longer than could be hoped for after an operation, even when successful. With this end he has recourse to intestinal washings with antiseptic solutions, so as to arrest, or at least diminish, the progress of the malady by removing the pus and secretions frequently. A solution of naphthol—ten to twenty centigrammes per cent.—is what he advises. In addition to this he disinfects the intestinal canal by exhibiting salol or benzonaphthol with bicarbonate of soda, in wafers by the mouth. Laxatives must also be given to prevent any accumulation in the colon, and M. Beaumetz is of opinion that a diet consisting largely of vegetables is also advisable. He has at present under observation three patients suffering from rectal cancer, who for the last three years have been subjected to this method of treatment, and who have even gained in flesh. He is satisfied that the method is superior to extirpation.—*Lancet.*

An Aged Actor.—The author of a book recently published, entitled "The Gossip of the Century," writes that he had often heard his father describe the performance of *Shylock* by Macklin when the actor was in his one hundredth year. This occurred May 7, 1789. Macklin was born in 1690, and survived his remarkable presentation of *Shylock* eight years.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, November 19, 1892.

OPERATIONS ON THE AGED.

SOME years ago Professor, afterward Sir George, Humphry, of Cambridge, in his study of the statistics furnished by a collective investigation of old age, had his attention drawn to the great recuperative powers of those long past middle life, and was led to make this a subject of more particular investigation. He found many striking instances of the rapid healing of ulcers, wounds, and fractures in the aged, which caused him to modify the opinion which he had hitherto shared with the profession at large concerning the low reparative powers of old people. He studied the statistics of various illnesses also, and found that the instances of recovery from acute diseases and their effects were surprisingly numerous among the aged. Indeed, Sir George concluded that the tendency of physician and friends to give up all hope when disease seized upon an individual seventy years of age and over, was without foundation in fact, and insisted that life could often be prolonged in such cases even when they seemed to be most desperate.

A similar subject, namely, the recuperative powers of the aged after surgical operation, has recently been investigated by Dr. Blum, who has published the results of his studies in the *Archives Générales de Médecine* for July, 1892. He has collected a series of fourteen major operations upon old people, only one of which had a fatal issue, and concludes from his analysis of these cases that the chances of success are fully as great in the aged as in those of fewer years. The result, he says, depends less upon the age of the patient than it does upon his previous condition of health, and he counsels operation not only when life is directly menaced, as in the case of strangulated hernia, for example, but even when there is less imminent danger, as when the presence of a slowly growing tumor points to a fatal result in the more or less distant future.

There are, of course, certain special precautions to be observed in operating upon the very old, which may be omitted in the case of the more robust. For example, it is advisable, when possible, to devote some little time to toning up the general system by food and the judicious use of tonic remedies. General anæsthesia should also be avoided when practicable, and fortunately this is often possible, as the aged are less susceptible to pain than the young and middle-aged. Extra precautions should also be taken to avoid chilling of the patient by unnecessary exposure of the surface of the body beyond the actual area of operation. Another practical point to be borne in mind when preparing for operation on the aged, is that the nervous system in general, and with it the vaso-motor, is less tolerant of insult, hence the attempt to obtain a bloodless field of operation is inadvisable. The pressure of the Esmarch bandage may lead to vaso-motor paralysis, and a secondary hemorrhage may be the result—a hemorrhage difficult of control by reason of the atheromatous condition of the arteries. Finally, great care should be paid to the after-treatment of these aged patients, and the surgeon should see to it that they receive plenty of nourishing and easily digestible food, the "feeding-up" process beginning at once as soon as the operation is concluded and the immediate shock of it is over.

It is well to bear the fact in mind that an old man or an old woman need not suffer from a chronic, and probably eventually fatal, surgical malady for long years, simply through fear that any attempt at relief would shorten life. The sufferings of the aged seem more pitiful than those of the younger man, and it is one of the greatest privileges of the surgeon to be able to relieve them. Now, indeed, he need not refuse his aid in all but the most desperate cases, but may operate, observing the special precautions above referred to, when the object is not purely to save life, but simply to relieve suffering and to render life less of a burden.

DOCTORS ON THE CONGO.

IT is a common saying among unthinking people that medical science has, after all, done little for humanity; that disease still runs its course with little or no check, notwithstanding the so-called progress of medicine. It is easy enough to refute such statements and to show by elaborate statistics that the science of the prevention of disease has made gigantic strides in these latter days, even though that of cure seems to the superficial observer to be lagging. But we need but one small incident to show what medicine—the science of medicine—may accomplish in the economy of human life. We find it recounted briefly as an item of news in the *Sun* of recent date.

When the building of the railroad in the Upper Congo was begun, one of the first cares of the company undertaking it was the organization of a medical staff. Besides the many hundreds of native laborers there were some two hundred and fifty white men in the employ of the company, and to look after the health of these a staff of five medical men was organized. The medical officers were given large powers in the way of regulation of the daily lives of the employees of the company, and in addition to the care of the sick, they saw to it that the buildings erected were built on correct sanitary principles. The laborers' camps, which from the nature of the work were being constantly advanced along the line of the growing road, were also carefully inspected from time to time, and maintained in as hygienic a condition as possible. The water-supply also was looked after, the use of the Congo River water being prohibited, and, in order to diminish as far as possible the danger of malarial infection, only boiled water was allowed for drinking purposes. A commodious hospital was erected at Matadi, and all the sick were at once removed there for

treatment. One of the staff was also always present in the laborers' camps to take care of all emergency cases, whether medical or surgical.

It might be thought that the company was very philanthropic, or that it felt a truly paternal solicitude for those in its employ. Possibly. But it found its substantial reward in the diminished sickness of the men, and in the consequent increased efficiency of the force, for the saving in time thus brought about paid many times over the salaries of the medical staff. The health of the white men has been fairly good in spite of the climate and of the fact that a pre-eminently malarious country was being broken into for the first time, and the number of deaths among them has been proportionally far below that of any other body of Europeans residing on the Congo in previous years. The health of the native workmen has also been very much above the average.

Simple arguments are sometimes more effective than elaborate ones, and we have seen none recently which shows more forcibly the good done by medical science than this brief tale of the work of the doctors in the centre of the Dark Continent.

THOMAS NEILL CREAM, THE STRYCHNINE FIEND.

The trial and condemnation of this man for poisoning prostitutes with strychnine has given rise to a good deal of medico legal discussion. Regarding the man's insanity, it seems to be agreed that, while such a person could hardly have the same kind of mind as a sane person, yet he knew the nature of his acts, was not influenced by any delusion, and was legally responsible. Such persons must be either destroyed or forever put away from society.

Cream's various experiments in strychnine poisoning seem to have begun in Chicago eleven years ago. At his trial for murder then, it was proved that the prisoner, acting in concert with a Mrs. Stott, with whom he had criminal relations, filled capsules with strychnine and caused these capsules to be given to Mrs. Stott's husband, who was afflicted with epilepsy; the death that followed was ascribed to a "fit." At the earnest solicitation of "Cream," or Neill, who desired a correct diagnosis for the purpose of blackmail, the body was exhumed, and 3½ grains of strychnine found therein.

In the recent trial the defence attempted to make a point with regard to the length of time required for strychnine to act. The evidence seemed to show that the poison was given to Clover a little before 10 P.M., and at 3 A.M. she aroused the household by her screams. It is probable enough that the woman would suffer some little time in comparative silence, hence all that can be said is that the symptoms began between four and five hours after the dose. In recorded cases in which the strychnine was given in solution or as a powder, as a rule the symptoms have come on, as Dr. Stevenson in his evidence stated, within the hour. In a case recorded by Barker, the symptoms commenced within three minutes, but, on the other hand, there are recorded cases in which three hours have elapsed. The defence also raised the question as to the rigidity of the body after death. It was affirmed, says the *British Medical Journal*, that a person poisoned by strychnine would be after death preternaturally rigid, and there was a suggestion that that rigidity would be more or less permanent. It is accepted that, as a rule, *post mortem* rigidity after strychnine poisoning sets in rapidly; but, on the other hand, it has been known to disappear within twenty-four hours. In a great proportion of the cases recorded of death by strychnine there is no special mention of rigidity, the natural inference being that the observers noticed nothing unusual—nothing different from the majority of ordinary *post-mortem* appearances.

On the whole the points which the defence attempted to make were thoroughly met, and the verdict appears to have been fully justified.

GENIUS AND INSANITY.

Some poets speak the truth even when writing prose. In the October *Century*, Mr. E. C. Stedman says of *The Faculty Divine*: "Genius of the more universal type is marked by a sound and healthy judgment. You may dismiss with small respect the notion of Fairfield, Lombroso, and their like, that genius is the symptom of a neurotic disorder, that all who exhibit it are more or less mad. This generalization involves a misconception of the term: they apply it to the *abnormal excess, the morbid action of a special faculty*, while true genius consists in the creative gift of one or more faculties at the highest, sustained by the same co-operation of the possessor's other physical and mental endowments."

INSOMNIA AND MENTAL DEPRESSION.

A promising young English writer, Amy Levy, has given a realistic picture of insomnia and mental depression, in some verses designed for the epitaph of a commonplace person who died in bed. Every physician will do well to read, mark, learn, and inwardly digest them, in order to gain a little insight into the mental state due to exhaustion of nerve-centres, that gives a sense of complete isolation equal to the loneliness of the shipwrecked in mid-ocean. The earthly loneliness of Amy Levy ended less than four years ago. She committed suicide shortly after the appearance of a powerful sketch called "Ruben Sachs," in which are handled without gloves the failings of the modern Hebrews, her own people. Here are the lines concerning the commonplace person:

> He will never lie on his couch awake,
> Wide-eyed, tearless, till dim daybreak;
> Never again will he smile and smile,
> When his heart is breaking all the while;
> He will never stretch out his hands in vain,
> Groping and groping—never again;
> Never ask for bread, get a stone instead;
> Never pretend that the stone is bread;
> Never sway and sway 'twixt the false and true,
> Weighing and noting the long hours through;
> Never ache and ache with the choked-up sighs;
> This is the end of him—here he lies.

In mental depression, psychic aid must come from the physician himself. He must be at once the doctor of the soul and the doctor of the body. The sensitive are never sensible when overthrown by the affairs of daily life. They need help from others in order to get the correct proportions of things, help having for chief ingredients earnestness, sympathy, firmness, and good judgment. All this need not necessarily be expressed in words, but it

must constitute an atmosphere of cheerfulness and goodwill. And if by chance the physician in charge knows more of knives and chemical compounds than of the human mind, let him frankly confess it, remembering that one star differeth from another. It is well to recognize the fact that neurasthenia may complicate some obscure condition that causes death, and that mental depression in itself may lead to suicide. Whether life is worth living is a question with everyone at times. When decided permanently in the negative by the weak of physique and depressed in spirit, it is wise to consider the possibilities of the situation.

THE TIE THAT BINDS, AND CHRISTIAN SCIENCE.

We are compelled regretfully to chronicle the sorrowful fact that Christian Science has been grossly insulted by the law, a certain judge having ruled that it may be, under certain conditions, inimical to health and a sound mind. It appears that the divorce law in one of the New England States permits of the dissolution of the marriage tie when one of the parties acts in such a way as to endanger the health, mental or physical, of the other. Basely taking advantage of this provision of the law, a man, not long ago, applied for a divorce on the ground that his wife was a convert to Christian Science and practised faith-curing. It was not held that she had tried her science on him, but he disapproved strongly of her latest fad, and alleged that her espousal of the new doctrine had made him unhappy, glum, and generally cranky. He produced an array of medical expert testimony to the fact of his despondency and growing bad temper, and the witnesses stated as their belief that further brooding on the Christian scientific doings of his wife would imperil his reason as well as endanger his health. His wife said he was only "in belief" and she thought that a little application of her science, *secundum artem*, would take that belief out of him in short measure. Her diagnosis was not accepted, however, and the divorce was granted forthwith. There is, therefore, now, legal precedent for considering a belief in Christian Science a possible cause for divorce, for this decision of the judge places its practice, *quoad* divorce, on a level with incompatibility of temperament and other things.

SEA-SICKNESS.

One of the most obstinate of ailments and most trying to the self-sufficiency of the infallible therapeutist is sea-sickness. This is not because there are not enough remedies for it, for if only one-twentieth of those recommended could be relied upon as efficient the malady would become but a memory and the sea would be robbed of its greatest of terrors. But we are not going to inflict a treatise on sea-sickness upon the patient reader, wishing simply to put on record, for the benefit of American voyagers, a preventive measure proposed by Dr. Ames Brunton in the *British Medical Journal* of recent date. This consists in the applying of a leather strap round the lower part of the thorax and epigastrium. It is put on previous to going on board, and is drawn very tight, and must be kept on till the traveller gains his "sea-legs." This hint, Dr. Brunton says, he "obtained from a gentleman who was previously a martyr to sea-sickness, but now in his frequent journeys across the Channel makes them with comfort and triumph, and, needless to say, perfect immunity from sickness. If necessary, a pad over the epigastrium can be added. It is possible that the compression over the liver may have something to do with the beneficial action of the strapping, which prevents the sinking which heralds the nausea."

We have no fault to find with the simplicity of this means, and the writer claims that it is as efficient as simple, being "in the great majority of cases an absolute preventive of sea-sickness." Possibly it is, yet we cannot but wonder why, then, our sweet sisters, whose dear little epigastria are tightly, and often even painfully, compressed by the cruel corset, should suffer so universally from this most distressing and unromantic of ills.

News of the Week.

The Wesley M. Carpenter Lecture.—The Wesley M. Carpenter lecture will be delivered on Tuesday evening, November 22d, at eight o'clock, at the New York Academy of Medicine, 17, 19, and 21 West Forty-third Street, by J. J. Kinyoun, M.D., Marine Hospital Service, Washington, D.C. Subject: "Modern Treatment of the Infected Vessel." Fellows of the Academy and the profession in general are cordially invited to attend.

Eleventh International Medical Congress. — The American Sub-Committee has the following membership: W. T. Briggs, Nashville, Tenn.; H. P. Bowditch, Boston, Mass.; S. C. Busey, Washington, D.C.; C. Cushing, San Francisco, Cal.; N. S. Davis, Chicago, Ill.; A. Jacobi, New York, chairman; Norman W. Kingsley, D.D.S., New York; Wm. Osler, Baltimore, Md.; Wm. Pepper, Philadelphia, Pa.; F. Peyre Porcher, Charleston, S.C.; Charles A. L. Reed, Cincinnati, O.; D. B. St. John Roosa, New York; Alex. J. C. Skene, Brooklyn, N. Y.; and James Stewart, Montreal, Canada. The secretary general informs the committee that the French Railway Company has offered to the members of the Congress a reduction of fifty per cent. on its fare.

Dr. William C. Jarvis, of New York, has been elected Professor of Laryngology in the Medical Department of the University of Vermont.

The Alvarenga Prize for 1893.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about one hundred and eighty dollars, will be made on July 14, 1893, provided that an essay deemed by the committee of award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the secretary of the college on or before May 1, 1893. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within it the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be

returned upon application within three months after the award. The Alvarenga prize for 1892 has been awarded to Dr. R. H. L. Bibb, of Saltillo, Mexico, for his essay entitled, "Observations on the Nature of Leprosy."

The Examinations for the Medical Department of the United States Army.—The examination of candidates for commissions in the medical department of the army, recently held at the army headquarters in this city, was not, says a writer in *The Tribune*, prolific in its results. Only four of the twenty-two who appeared before the Medical Board succeeded in filling the rigid requirements, professional and physical, for appointment as assistant surgeons. The officials of the Medical Department are gratified for the few successful candidates, considering their high qualifications, but they are also disappointed at the small percentage of the successful ones. On the other hand, the applicants who failed in the examinations, and also their friends, feel their disappointment more keenly and complain bitterly about the severity of the examination. The Surgeon General's Department, however, prefers to go shorthanded than reduce the standard of the examination, and soon another examination will be ordered to fill the six vacancies still remaining.

Working for Good Roads.—The following petition is being widely circulated, and it is hoped that at least a million signatures to it will be obtained before the first of the year :

"*To the Honorable Senate and House of Representatives in Congress assembled :*

"We, the undersigned, citizens of the United States, hereby most respectfully petition that there be founded in the city of Washington, in the District of Columbia, a Road Department, similar to the Agricultural Department, for the purpose of promoting knowledge in the art of constructing and maintaining roads ; and we ask that in such department provision be made for teaching students so that they may become skilled road engineers. In connection with this Road Department we request that there be established a permanent Exhibit, in which shall be shown sections of roads illustrating various methods of construction, and also the best road materials and machinery.

"We further petition that Congress appropriate funds sufficient to erect a building at the World's Columbian Exposition for the purpose of a comprehensive road exhibit."

Those desiring blanks to sign may obtain them from Mr. Albert A. Pope, P. O. Box B, Boston, Mass.

To Fast for a Medical College.—Arthur W. Wuellmeas, a Frenchman, will begin a fifty-day fast in Cleveland, O., under the auspices of the Western Reserve University Medical College. Wuellmeas has fasted four times before. The first was in Chicago, in 1890, when he went twenty-one days without taking food. Later the same year, he fasted thirty days at Detroit. We trust that the good faster may give the students some points for post-graduate experiences.

Leprosy is a disease which seems to stimulate with especial intensity the philanthropic imagination. Father Damien was made quite a saint, though, barring sentiment, he could not have been a very pleasant or altogether heroic man. Sister Rose Gertrude set out with a great flourish of trumpets to relieve the lepers of Hawaii, but soon dropped into the arms of matrimony in a most commonplace father. The work of Miss Kate Marsden, however, among the Siberian lepers opened a new field, and appears to have been arduous, self-sacrificing, and fruitful. She comes to America soon, to present her cause to us.

The Diagnosis was Deferred.—"Madame," said the doctor, in response to the earnest inquiry of his patient, "you are suffering from a complication of disorders, the exact nature of which can only be ascertained at the post-mortem."

Swallowed Cholera Bacilli.—Professor Pettenkofer and Professor Emmerich, who have been conducting a series of experiments with cholera bacilli, say that, as far as they have been able to learn, local, and not individual conditions, engender the epidemic. Both men have swallowed large numbers of cholera bacilli, and yet, but for slight diarrhœa, neither of them suffered any inconvenience. The result of the experiments was a surprise to Professor Pettenkofer, whose theory formerly was that the taking of any large number of comma bacilli into the system would be followed by cholera.

The Quarantine in this Port against cholera is likely to last for a long time, or until no more cases of the disease occur in European ports.

International Monument to Semmelweis.—A meeting was held in London recently, under the presidency of Sir Andrew Clark, the object of which was to combine with all admirers of Semmelweis—"the father of antiseptic midwifery"—to raise in his native city of Buda-Pesth a monument to this great pioneer of antisepticism. It is nearly fifty years since Semmelweis demonstrated the septicæmic nature of puerperal fever, and for many years his work was appreciated by only a few followers and his name was almost forgotten. His professional brethren in Hungary have now determined to raise by international subscription a memorial to their distinguished countryman, who, like many a martyr, was not appreciated while he lived.

A Curious Bequest.—Dr. W. F. Cumming has bequeathed the sum of $3,000 to the Edinburgh Royal Infirmary, the income to be used in purchasing tobacco and snuff for pauper patients.

Monument to the "Reviver of Transfusion."—A month ago, at Domène, a monument erected in memory of Dr. Marmonier, senior, who for nearly half a century has practised medicine in that little town, was unveiled in the presence of a large number of doctors. The monument is in the form of a beautiful fountain. From the centre of the basin rises a pyramid surmounted by a bronze bust of Dr. Marmonier. Upon the principal façade is the inscription : "To Doctor Marmonier, Senior, who Revived Transfusion of the Blood." ("Au Docteur Marmonier Père, Rénovateur de la Transfusion du Sang.")

Reappearance of La Grippe.—There is an unusual prevalence of catarrhal troubles during the present autumn, bearing a resemblance to sporadic cases of grippe, and two deaths from the latter disease have been reported.

Hypnotism has another organ, called *Zeitschrift fur Hypnotismus, Suggestion und Therapie, Suggestionslehre, und verwandte psychologische Forschungers.* It is edited by Dr. J. Grossmann, of Konitz, and published in Berlin. Paris has also its journal, and it looks as though hypnotism had come to stay.

Dr. Frederick H. Wiggin has been appointed one of the physicians of the Board of Education vice Dr. F. W. Olds, resigned.

Pharmaceutical Law in Guatemala.—At a recent meeting of the pharmacists of Guatemala, *La Escuela de Medicina* states, the governing committee directed the secretary to call the attention of the members to certain laws, the provisions of which had not been strictly observed of late. These laws provide that pharmacists shall not dispense, without a physician's prescription, any drugs except those in common use in domestic medicine, and which even physicians are accustomed to prescribe verbally. Even on a prescription they must not dispense any poison in large dose without previously calling upon the physician and ascertaining that the prescription is written as intended. The same precaution shall be taken when incompatibles are prescribed in the same mixture. Prescriptions written more than a week before being presented shall not be compounded. Finally, no druggist is allowed, without the permission of the prescriber, to give a copy of any prescription to any person whomsoever, unless ordered to do so by the authorities.

A Practical Transilluminator.—In the article on this subject, by Dr. Chevalier Jackson, in the issue for October 29th, in the ninth line from the end, "single-current" should read "single curved."

"**La Escuela de Medicina**" is the title of a new journal, published in Guatemala, devoted to the interests of the physicians and pharmacists of that republic. Various medical journals have been started in that uneasy little State since 1855, but have ceased to exist one after the other, some for political reasons, others for lack of support. We hope for a longer life for our new contemporary, and we hasten to extend to the distinguished editor the assurances of our esteemed consideration and best wishes for success in his noble undertaking.

Happy London.—The number of medical practitioners in London, in proportion to the population, is only about one to each thousand persons. The average clientèle of a practitioner in that blessed city is, therefore, at least twice the size of his New York brother. The number of dispensary patients in London is smaller in comparison with the population than it is in New York. And yet the ungrateful Londoner complains that the profession is overcrowded!

The Medical School of the Tokio Charity Hospital began its winter session on September 15th. The progressive character of the school is evidenced by the fact that women are admitted on an equality with men.

Water at the Fair.—The citizens of Chicago or, at least, the World's Fair Commissioners, have discovered the fact that the drinking-water supplied to their town is not exactly to be commended as a hygienic beverage. They have made an arrangement with a natural spring company, in Wisconsin, to supply the drinking water for the Fair grounds, and as the water is obtained over a hundred miles from Chicago, it may be pretty confidently pronounced drinkable.

The Sabathu Leper Asylum.—We have received the report of this institution for the year 1891, during which year eighty-seven lepers found refuge in the asylum. Dr. M. B. Carleton, the superintendent, would be glad to answer any inquiries concerning the disease that may be addressed to him. He would be glad also to receive any donations in aid of the asylum. The cost per annum for each leper is about $25. Dr. Carleton's address is Sabathu, North India.

Obituary.

GEORGE ROSS, M.A., M.D.,

VICE-DEAN OF THE MEDICAL FACULTY OF MCGILL COLLEGE, MONTREAL, CANADA.

Dr. George Ross, aged forty-seven years, died at his residence, Montreal, on Tuesday, November 8th. He had an attack of paralysis two years ago, and had been in failing health ever since, being confined to his room for the past four months.

Dr. Ross was one of the most distinguished members of the profession in Canada. He was born in Montreal, and received his education in his native city, graduating at McGill College in 1866. After three years' private practice in Montreal he was appointed professor of Hygiene and Public Health at McGill, and in the following year took the chair of Clinical Medicine. He succeeded the late Dr. Howard in 1889 as professor of Practice of Medicine, a position he filled with great acceptance. He was for many years on the editorial staff of the *Montreal Medical Journal.*

Dr. Ross was a prominent member of many medical associations, was president of the Canadian Medical Association in 1888, and several times president of the local association in Montreal. He was governor of McGill University, which he represented as a member of the College of Physicians of the Province of Quebec.

To medical literature Dr. Ross contributed many valuable works in the way of papers, lectures, and articles published in medical journals, besides his well-known contributions to many of the extensive systems of medicine published in recent years. As a consultant he had a national reputation, and his successful professional career was so free from blemish that it can well serve as a model for careful imitation.

The death of Dr. George Ross removes from the medical profession of Canada one of its most honored and beloved members. Although comparatively a young man, the twenty-six years of his life as a medical practitioner furnish the much-needed lesson that the highest aims of human endeavor are most effectually realized in the good we can do to others. Dr. Ross's rare and estimable qualifications as a high-minded physician, and his lovable character as a man, when his friendship was secured, won for him the respect and esteem of all who delight to honor an educated and cultivated gentleman. His medical confrères in Montreal had for him more than an ordinary affection, and will long cherish his memory as that of a wise physician and a chivalrous gentleman, whose name will ever remain a synonym for all that is noblest and best in our profession.

Electrocution in France.—A motion has been made in the French Senate to substitute death by electricity for the guillotine. The member who proposed it did so on the ground that this mode of inflicting the death penalty had been eminently successful in New York State.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 3, 1892.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

Abnormal Conditions of Organs and Tissues Contained within the Abdominal Cavity which Simulate and may be Mistaken for Diseases of the Uterus and its Appendages.—DR. W. GILL WYLIE said his paper would not follow strictly the title given it, as it was his intention to refer to some of the changes in gynecological practice and the causes leading thereto the past ten years. Reference was made to some papers he had read eight years or more ago, predicting some of the changes which would be made and in line with views which he then expressed. For instance, a great deal of discussion and work centred some years ago about what was called chronic pelvic cellulitis—a condition which practically did not exist, the real state being, as a rule where interference was called for, disease of the tubes and ovaries. This view, expressed by him more than eight years ago, was generally accepted to-day. He had also predicted that before many years gynecologists would come to recognize the exaggerated importance which they had attributed to uterine displacement. Later, in a paper on anteflexions, he had stated that the displacement was not the cause of most of the symptoms, but rather a chronic endometritis and indurated state at the cervix and above, and that the treatment called for dilatation and drainage rather than replacement. While text books still gave some importance to cellulitis and displacements, it should be remembered that writers of text-books were not always so progressive as those who were more noted for practice than for literary tendencies. Text books did not reflect present views so well as did society discussions and monographs.

The author then took up the consideration of certain facts which laparotomy practice had incidentally enabled him to establish. One was that the gynecologist who undertook to cure minor uterine diseases should have a good knowledge of rectal diseases, and know that these, and also changes in other organs, might produce symptoms heretofore regarded as belonging to diseases of the genitalia alone. Prolapsus of the intestines, displacement of the kidneys, fecal impaction, etc., might cause symptoms which one might be misled to regard as of uterine origin alone. In nineteen cases out of twenty of retroversion of the uterus, with symptoms, there was salpingitis or ovaritis, and if it were possible to break up the adhesions without opening the belly for the purpose of replacing the uterus, it would result in an acute attack of peritonitis. In many of the cases the omentum and intestines were prolapsed, crowding into the pelvis. There was also likely in such cases to be displacement of the right kidney. In many cases on opening the abdomen he had found the omentum six to twelve inches longer than was supposed to be normal, the blood-vessels enormously enlarged, the whole constituting a thick mass like a tumor. Among the rectal conditions, simple or complicated by displacement of the abdominal contents, which caused symptoms simulating uterine disease, were a tendency to crack at the anus on slight pressure, the presence of hæmorrhoids, hyperæsthetic spots on the mucous membrane, an irritable condition of the sphincter with pressure upon the diseased membrane causing great pain; the sphincter refusing to open caused pain on defecation, so that the patient was led to put the act off as long as possible. The fæces came away in round, hard balls, or there might be alternate constipation and diarrhœal tendency, without, however, complete clearance of the bowel.

He had often found some abnormal condition of the rectum, a hyperæsthetic spot about the cæcum, displacement of the stomach, intestines, omentum, or kidneys, in cases that previously had been treated for uterine trouble alone, which in reality had little to do with causing the symptoms. It was his custom, when the symptoms were not evidently due to some abnormal state of the generative organs, to send the patient from his examining-table to a room where she could strip completely, go to bed, and be in shape for thorough examination of all the abdominal organs. If necessary, he even gave ether in order to determine the exact state of the kidneys, etc. Movable kidney was present in twenty to thirty per cent. of the women seen in his private practice. To determine the position and size of the stomach and colon, it was only necessary to fill them with air. He would not do nephrorrhaphy for movable kidney until uterine and rectal troubles had been corrected. The time would come, sooner or later, when a thorough study would have to be made of the rectum and kidneys by all students of gynecology.

Has a Woman Pelvic Cellular Tissue?—DR. PAUL F. MUNDÉ said he agreed with much that the author had written, but there was one difference between them—the author seemed to think there was no pelvic cellular tissue. If there was, how could it be otherwise than that sometimes it was the seat of cellulitis? A woman has other organs besides pelvic organs. He was glad Dr. Wylie had brought to the attention of a general medical society the fact that a woman had other organs besides pelvic organs. There was a great deal too much tendency to attribute all of woman's ills to her genitals. The author had referred to a number of conditions which might simulate disease of the sexual organs, and Dr. Mundé said he had seen examples of those conditions. Besides these he might mention some others. Proctitis was not unusually the cause of symptoms simulating uterine disease. Painful micturition might be attributed to uterine trouble when really due to fissure of the urethra or caruncle. Pain in the back might be due to a disease of the coccyx. Pain across the abdomen, extending from side to side, below the umbilicus, was often present in women of constipated habits, and due to a colitis. Dilatation of the stomach produced symptoms which might be mistaken for disease of the genitals. As to the kidney, more frequently would the ureter be found at fault. He related cases where a stone in the ureter has misled the doctor to treat the genitals. There might be displacement of the liver. Accumulation of fecal matter had been mistaken by him and others for tumor of the uterus or its appendages; the same was true of tumor of the liver, of cyst of the mesocolon, tubercular peritonitis, etc. As to displacements of the uterus, he said they in themselves amounted to little, it was the adhesions and complications that made them important, although the complications might require replacement of the uterus for their correction.

DR. H. J. BOLDT thought that by the present time gynecologists, as well as general practitioners, knew there was something in woman besides the uterus and its appendages. Of displacements causing symptoms simulating those of uterine disease, movable kidney was most important. Low displacement of the right kidney caused not only reflex symptoms, but also constant pain except in the horizontal position. A chronic inflammatory state about the vermiform appendix was sometimes the cause of symptoms which might be mistaken for genital trouble. A painful state of the abdominal muscles was liable to be mistaken for pelvic difficulty. He had known them to form knots or tumors which simulated tumors more deeply situated. The ureters were easily palpated in subjects whose muscles were fully relaxed, and were often found of double the normal thickness, and the cause of bladder symptoms.

Tumors of the Omentum Mistaken for Pelvic Tumors.—DR. EDEBOHLS had elsewhere presented specimens illustrating a hypertrophied, congested, and œdematous condition of the omentum, forming tumors which had

been diagnosticated as fibroid tumors of the uterus. He had seen two cases of misplaced or wandering liver, causing symptoms much like those attending uterine disease. The conclusions to be drawn from the discussion was that to-day the gynecologist had also to be a good general practitioner. He would go further than Dr. Wylie and commence the examination of all cases at the abdominal organs, proceeding thence to the pelvic organs, since, if one begin with the latter he might be satisfied with what he there found, and not know of the existence of movable kidney, etc.

Uterine Displacement Does Produce Symptoms.—Dr. A. P. Dudley said he still believed uterine displacement in itself might produce reflex troubles of more or less serious nature. This could be explained by the disturbance of the circulation brought about by displacement. He further placed stress upon adhesions as a cause of symptoms. He had seen some cases of cancer of the pancreas which had given a history which might have been supposed due to pelvic disease. Displacement of the spleen might simulate ovarian trouble; so might disease of the gall-bladder. Syphilitic disease of the rectum, high behind the uterus, had been mistaken for uterine disease, abnormal shortening of the utero-sacral ligaments sometimes caused traction upon the bladder and painful micturition. He had seen several cases of papilloma of the omentum and mesentery simulate ovarian trouble. Abdominal hernia and angioma ought also to be mentioned.

Movable Kidney Seldom Found at Autopsy.—The President said it would seem from the discussion that movable kidney was very common, yet about three years ago he requested the curators of Bellevue Hospital to make special examination with regard to this point at autopsies, and thus far they had found movable kidney in only three cases.

Dr. Wylie said, in closing, that he did not deny the existence of cellular tissue in the pelvis, but believed there was no such thing as chronic pelvic cellulitis. He had purposely left out the question of abdominal tumors. Displacement of the uterus interfered with the circulation only when there were adhesions.

Regarding a tumor-like condition, or hypertrophy of the omentum, this was likely to disappear after any necessary operation on the appendages, etc., as he had proven in some cases where secondary laparotomy had been performed.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 26, 1892.

H. P. Loomis, M.D., President, in the Chair.

Pott's Disease, Associated with Fibrinous, Peritoneal, and Pleuritic Adhesions.—Dr. H. S. Stearns presented a specimen, showing the diseased vertebra from a case of Pott's disease. The specimen was not of special interest in itself, and his only object in presenting it was to elicit a discussion on an associated condition. The patient was a colored man, thirty-five years of age, who for three years past had suffered from pain in the back, consequent upon caries of the spine. When admitted to the hospital last May, there was considerable deformity of the spine, with partial paralysis and marked anæsthesia of the lower extremities. He died on October 25, 1892, and at the autopsy it was found that there were old fibrous adhesions in the pleural and abdominal cavities, sufficient to almost obliterate these cavities. The lungs were removed with difficulty, and the intestines were extensively matted together. There was no fluid in either cavity, and careful search failed to show any tuberculous lesions either in the intestine or in the lungs. The liver was of normal size, but was pressed upward on the right side above its normal position. There was no pus found anywhere except at the seat of the disease in the spine, where an abscess cavity was found extending up alongside of the affected vertebræ. Some of the adhesions in the peritoneal cavity were of comparatively recent formation. Dr. Stearns asked for an expression of opinion as to the cause of this fibrinous exudate.

Dr. H. M. Biggs considered the case to be one of tubercular peritonitis and pleuritis, with disappearance of the tubercular lesion and the formation of fibrous adhesions. He had long believed that there was no variety of tuberculosis in which there was such a large percentage of spontaneous recoveries as in tuberculosis of the serous membranes; indeed, he believed that this was the termination of the majority of these cases, although he could not prove the correctness of his position. The original miliary tubercles being very small, they are lost sight of when the cells undergo degeneration, only fibrous tissue remaining, and there is nothing to stamp this process as tubercular. There is no question but that we find not infrequently in the cicatrization of tubercular processes in the lungs no vestige of this process except simply fibrous tissue, what might perhaps be called an "interstitial pneumonitis," yet from the history of the case, and from the nature of the surrounding tissue, there is every reason to believe that this fibrous tissue is the result of a tubercular process.

Dr. S. T. Armstrong did not think that this view was the one generally held, and he saw no reason for expecting a different pathological lesion in tuberculosis of the serous membranes from that found in tubercular processes elsewhere. Even in the stage of degeneration, there should be a recognizable lesion. The speaker referred to a very similar case to that just reported, which he saw ten years ago. He could not recall the details of this case, but he remembered that there was no history of traumatism, and that he had looked upon the case at that time as an instance of recovery from an idiopathic peritonitis.

Dr. R. H. Sayre said that he had exhibited to the society last year a specimen taken from the spine of a boy, who at the time of his death from tuberculosis had symptoms of beginning inflammation of the spine. In this case, the intestines were matted together into large masses by adhesions, and the retro-peritoneal glands were very much enlarged, yet there were no tubercles visible to the naked eye.

Dr. W. P. Northrup referred to a case of tuberculosis which he had observed during life, and upon which he had made an autopsy. No tubercle bacilli could be demonstrated, and only a few giant-cells were found, but all the pathologists who saw the case, among others, Dr. Francis Delafield, were of the opinion that the tuberculosis was well on the road to recovery. He was inclined to endorse in the main the views expressed by Dr. Biggs.

Sudden Death from Impaction of Meat in the Larynx.—Dr. H. M. Biggs presented a larynx removed from a man who had died very suddenly, and his object in presenting it was to give greater prominence to a not uncommon cause of sudden death, namely, the lodgement of foreign bodies in the larynx. This man, while sitting in a restaurant eating soup, was observed to cough suddenly and to have a slight convulsion, and in a moment he was dead. After hearing this history, and before making the post-mortem examination, the speaker had expressed the opinion, based on a dozen or more similar cases, that death in this case was due to suffocation from the presence of a foreign body in the larynx. An important point in the history is the occurrence of a slight convulsion. At the autopsy a very large piece of meat was found so situated as to absolutely occlude the larynx. Death certainly does not take place in these cases from suffocation simply, but whether or not it was due to a reflex inhibition of the heart's action he could not say. He had seen quite a variety of foreign bodies in the air-passages; thus, in one case a collar-button formed a complete ball-valve; in another a screw was found; in a third a toy balloon had been drawn into the trachea, and was inflated with each inspiration; in still another, a bronchial

gland had caused suffocation by discharging its contents into the trachea.

Hydatid Cyst of the Liver; Staining the Hooklets of the Echinococcus.—Dr. George P. Biggs presented a specimen of hydatid cyst of the liver, removed from an Italian, aged thirty-five, who died as a result of stab-wounds of the abdomen. No history bearing upon the specimen was obtained. At the autopsy, a cystic tumor was found occupying nearly the whole of the right lobe of the liver, and measuring 12 ctm. transversely, by 10 ctm. vertically, and 9 ctm. in its antero posterior diameter. The anterior wall of the cyst was only about one and one-half millimetre in thickness, and the posterior wall only about one centimetre from the posterior surface of the liver. There were no adhesions. The cyst was very tense, and on incision, a large quantity of perfectly clear, colorless serum was discharged. The cyst was lined by a thick white membrane, and contained a large number of echinococcus cysts. Microscopical examination of the scrapings from the lining membrane showed numerous typical scolices and hooklets.

Dr. Biggs said he had accidentally discovered a method of staining these hooklets while engaged last summer in examining microscopically some pus which had been aspirated from the region of the liver for diagnostic purposes. The examination at first showed only tyrosin crystals, and a large number of degenerated pus-cells, but after staining a slide for tubercle bacilli he was surprised to find a typical echinococcus hooklet which had been stained a bright red by the eosin. It had not been visible previous to the staining, and prolonged search afterward only showed three such hooklets on this slide. The existence of a hydatid cyst was afterward proven by operation.

Polypoid Hypertrophy of the Uterine Mucous Membrane, with Epithelial Degeneration.—Dr. H. J. Boldt presented two uteri which had been removed by hysterectomy on account of this condition. Both women had passed the menopause, and both had been curetted a number of times, but in view of the recurrence of hemorrhage, and the age of the patients, and the possibility of the existence of malignant disease, he had thought it best to remove the uterus. The report of the pathologist, Dr. W. H. Porter, showed that in the first uterus there was a well-defined papillary growth, over one and one-half inch in diameter, some of the larger papillary projections extending fully one half inch beyond the original mucous surface lining the uterine cavity, while the peripheral and smaller projections were little more than microscopic points. Microscopical examination of the sections, made at right angles to the mucous lining of the uterine cavity, showed the new growth to be composed chiefly of a polypoid mass, and the papillary projections covered by a thick layer of hypertrophied and somewhat degenerated epithelium, which had constituted the original follicular structure lining the uterine cavity. There was no evidence of new follicles having been developed. This condition of the epithelial structure, modern pathology has designated as "adenomatous hypertrophy of the uterine mucous membrane." There was no distinct evidence of the basement membrane having given way, nor was there any well-marked invasion of the underlying lymphatic spaces with epithelial cells, as is commonly found in neoplasms having a carcinomatous character. At several points, however, the basement membrane appeared to be on the point of rupturing, with the inevitable result of the development of a truly carcinomatous neoplasm. Such growths as these are hardly to be called adenomatous, for there is no production of new gland tissue; it is more correct to speak of the condition as a polypoid hypertrophy of the lining membrane of the uterus with epithelial degeneration. In all these cases there is a common tendency to steady progression, and ultimately to the formation of a truly carcinomatous neoplasm. The second specimen is very similar to the first, except that the growth is less distinctly polypoid in character, and there is more distinct evidence of its carcinomatous nature. The sections from this specimen showed marked proliferation or an angiomatous condition of the vessels in the muscular tissue of the uterus, immediately underneath the mucous membrane, with increase of connective tissue between these vessels, so that in many places the appearance was not unlike that presented by a round-cell and spindle-cell sarcoma. This condition, which has been erroneously called inflammatory, is unquestionably the result of increased nutrition from the dilatation of the uterine vessels. In this specimen the deeper lymphatics had been invaded by epithelial elements, and the evidence of a carcinomatous development was quite marked. These cases eventually undergo malignant degeneration, except in occasional instances, when the endometrium has been entirely removed with a sharp spoon.

Two Cases of Hysterectomy for Carcinoma, Complicated with Myomata, Double Hydrosalpinx, and Cystic Ovaries.—Dr. Boldt also presented two uteri removed for the above condition.

The first specimen was removed from a patient, fifty-three years of age, who for the past six months had had irregular uterine hemorrhages. Her attending physician, Dr. Henry Ruhl, made a clinical diagnosis of carcinoma, and referred the case to the speaker for operation. This diagnosis was confirmed anatomically before the removal of the uterus. Examination showed not only the presence of myomata, but also of much infiltration around the uterus, and the elasticity of this infiltration showed it to be the result of previous inflammation, and not of malignant disease. The uterus was removed by what Dr. Boldt called, "the ideal hysterectomy," namely, by bringing the stumps down into the vagina and suturing the wound in the vagina so as to entirely shut off the peritoneal cavity. Catgut ligatures were employed exclusively. In this operation the chances of sepsis are very remote and recovery is very rapid. This patient left the hospital on the tenth day. In the second case, a carcinomatous uterus containing a fibroid in its body was removed by the same method, and the patient left the hospital on the eighth day.

The speaker said that the entire uterus should be invariably removed in every instance when the microscopical examination had confirmed the diagnosis of malignant disease, no matter how limited this disease may appear to be, for it has been found that although there may be only a small area of disease about the portico or the cervix, independent nodules may exist in the body of the uterus. The mortality attending this operation is not great; he had lost only three patients out of forty-five cases of vaginal hysterectomy done for cancer, and some operators had reported a still lower mortality. Both the immediate and the remote results, however, must depend a good deal upon the early recognition of the disease and a prompt resort to a radical operation.

Dr. Boldt said that in three of his cases myomata had been associated with carcinoma in women in advanced life, and it was of such comparatively frequent occurrence that he was inclined to believe that the irritation produced by these myomata is prone to give rise to malignant degeneration.

The President and Dr. H. M. Biggs both stated that they had very rarely met with carcinoma and myoma in the same case.

Induction of Chloroform Narcosis during Sleep; Removal of a Shoe-button from the Nose.—Dr. W. P. Northrup said that a child of twenty-two months had been recently brought to his office on account of an offensive nasal discharge which had existed for some time. With an Escherich inhaler, chloroform was successfully administered without awakening the child, and then there was no difficulty in removing a shoe-button from the nose. So far as could be ascertained, it must have been in the nose for at least three months. The speaker emphasized the importance of examining the

nose for a foreign body whenever there has been a persistent and profuse discharge from one side of the nose.

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE QUESTION OF AMPUTATING FOR DIABETIC GANGRENE—TRAUMATIC VOLVULUS—THE TREATMENT OF THE PERITONEUM IN ABDOMINAL SURGERY—SIR RICHARD OWEN—THE EPIDEMIC OF SCARLET FEVER—DR. RICHARDSON ON INTRA-THORACIC AUSCULTATION—LARGE VULVO-VAGINAL CYST—COMPLETE ERASION OF THE ANKLE-JOINT—THE ANNUAL MEETING OF FELLOWS AND MEMBERS OF THE ROYAL COLLEGE OF SURGEONS.

LONDON, October 29, 1892.

THE last meeting of the Medical and Chirurgical Society was devoted to discussing the question of amputation for diabetic gangrene. The subject was introduced by a paper from Mr. Godlee. He remarked that the term diabetic gangrene was made to include several different conditions now beginning to be recognized. Modern surgical improvements had modified the views with regard to amputation for the disease. The determining causes of diabetic gangrene were the same as in other forms of gangrene, but the author particularly directed attention to three, viz.: Inflammatory conditions, arterial disease, peripheral neuritis. Inflammatory conditions included carbuncles, noma vulvæ, and rapidly spreading ulcers of the legs, as well as extensive sloughing of septic wounds. Atheroma of vessels was probably actually caused by glycosuria, and was certainly predisposed to by it: diabetics who drank alcohol were thus specially liable to degenerative changes in their vessels. Mr. Godlee pointed out that neither gangrene of the foot nor carbuncle occurred before early middle age, and suggested that this was because the arterial and nervous changes had not yet reached a very advanced condition, though it might depend on the well-known differences between the acute diabetes of childhood and youth and the more chronic disease of middle and old age. Peripheral neuritis was now generally recognized as being caused by glycosuria, and as giving rise to many neuralgic and other symptoms, which might be classified as motor, sensory, trophic, and vasomotor. The combination of sensory and trophic symptoms, sometimes called "tabetic," and giving rise to perforating ulcer of the foot, was a fruitful source of gangrene of the leg. The author believed that in most cases of so-called diabetic gangrene, the condition depended chiefly either on arterial disease or on peripheral neuritis. In the former case the disease progressed rapidly, and was accompanied with great pain; in the latter case progress was slow, and pain slight or absent. The former should be treated by amputation at or above the knee, because it had been shown that in these cases the degeneration almost always reached the knee, but that very often it extended no farther; the latter might either be left alone or treated by amputation close to the necrosed part. Mr. Godlee quoted with disapproval some of the views expressed in surgical text-books. He acknowledged, however, that no amount of antiseptic treatment would prevent diabetic coma, and that this might follow even trivial operations.

The President (Sir Andrew Clark) suggested that the dryness of the tissues in diabetes was possibly a cause both of the gangrene and of the neuritis.

Mr. Hutchinson remarked that he had, in a paper read some years ago, advocated amputation above, instead of below, the knee for gangrene. He had often operated on diabetics, and had not found the risks in such cases so much greater, as was generally considered to be the case.

Mr. Golding-Bird mentioned a case of locomotor ataxy with perforating ulcers of the foot, in which he had performed a Syme's amputation. He had chosen that operation as the condition was due to peripheral neuritis and not to vascular changes. The case did well, though another perforating ulcer appeared later just below the inner malleolus; this ulcer, however, was treated with nitric acid, and the patient slowly recovered. Mr. Golding-Bird thought his case confirmed Mr. Godlee's opinion that amputation might be performed in the near neighborhood of gangrenous parts when the gangrene was due to neuritis and not to vascular disease.

Mr. W. G. Spencer narrated the case of a man with diabetes who was passing from seventy to eighty ounces of urine in the twenty-four hours, containing from ten to twelve grains of sugar to the ounce, and who had suppuration of the olecranon fossa. Amputation was advised but refused. Later, the patient became comatose, and at the request of friends amputation through the upper third of the humerus was performed. The stump healed well, and it was noticed after the operation that the quantity of sugar passed had fallen to half a grain in the ounce. The patient was being treated with opium and was on a modified diet which was the same as before operation. Mr. Spencer said that in another case of diabetes he had seen recovery from a severe attack of erysipelas.

Mr. Harrison Cripps remarked that ten years ago the feeling among surgeons was decidedly against amputation for either diabetic or senile gangrene. Then came Mr. Hutchinson's paper recommending high amputation, but even that was no longer necessary now that the principles of antiseptic surgery were thoroughly understood. Mr. Cripps said that he had had to deal with four cases of diabetic gangrene within the last five or six years. In two of these, by keeping the parts properly protected, spontaneous separation occurred satisfactorily. In the other two the gangrene was spreading, and he amputated just above the ankle; perfect healing occurred in both cases. The arteries were atheromatous in one case.

Mr. Marmaduke Shield said he had seen four cases of what might be called spontaneous whitlow in diabetics. Serious results might follow if such cases were treated without strict antiseptic precautions. In several cases of rapid necrosis of the mastoid cells he had found sugar in the urine.

Mr. Treves mentioned two cases of diabetic gangrene in which death rapidly followed amputation. This was four years ago and the deaths might have been due to defective antiseptic dressings. He thought that in some cases of diabetes operations would prove exceedingly dangerous, even with the strictest precautions.

Dr. Drewitt remarked that diabetics were exceedingly liable to be attacked by micro-organisms of all kinds.

Mr. Rivington thought that amputation should be resorted to where gangrene was affecting the life of the patient.

Mr. Pearce Gould said he had recently amputated through the knee-joint for gangrene and suppuration extending as far as the middle of the leg in a diabetic subject. The stump healed well and three days after the operation the sugar had almost disappeared from the urine and since then there had only been a trace.

Dr. George Harley said it had often been noticed that when diabetics were suffering from severe disease or injury the sugar disappeared from the urine only to reappear when convalescence set in.

Sir Andrew Clark said he had known this to occur in several cases of typhoid fever he had seen.

Mr. Treves, in answer to a question from Mr. Rivington, said that in both his cases high amputation had been performed, and both the cases had been in the medical wards for some time previous to operation.

Mr. Godlee then replied. He thought there was not enough known to make any definite statement as to the dryness of the tissues. The antiseptic precautions he

adopted were as follows: the limb was first washed with soap and water, carbolic acid solution, and corrosive sublimate solution (1 to 500), as high as the buttock; hands, instruments, etc. with carbolic acid solution; and, finally, the stump with corrosive sublimate solution (1 to 500). The stump was dressed with Lister's double cyanide dressing. Referring to the question as to whether in his first case the gangrene was due to the diabetes, he said he thought the immediate cause was atheroma of the vessels.

At the Medical Society Mr. G. R. Turner read notes of the case of a boy, aged seven, in whom abdominal pain and fecal vomiting followed a severe blow on the abdomen caused by a fall of twelve feet. The abdomen was opened within twenty-four hours of the accident and a volvulus of the small intestine discovered and unravelled. The patient made an uninterrupted recovery, which Mr. Turner attributed to the fact that the operation was performed before abdominal distention or intestinal adhesion had taken place. Dr. Hawkins and Mr. Staveley related two somewhat similar cases in which twisting of the gut followed abdominal injury and ended fatally. A discussion then took place on the treatment of the peritoneum in abdominal surgery, in which Mr. Meredith, Mr. Alban Doran, Mr. Shield, and Mr. Malcolm took part. Mr. Meredith thought that any unnecessary injury to the peritoneum should be avoided, but, as Mr. Doran remarked, the question turned on what constituted unnecessary injury. Mr. Malcolm thought the peritoneum would stand any amount of handling if it were kept aseptic. Mr. Meredith observed that rough sponging often did good in tuberculosis of the peritoneum by removing the serum and altering the nutrition of the membrane.

On Wednesday evening last a dinner was given to Sir Walter Foster, M.P., M.D., to congratulate him on his appointment as Parliamentary Secretary to the Local Government Board. This is an important post, though the holder of it does not have a seat in the Cabinet. The dinner was largely attended. In proposing Sir Walter Foster's health, Dr. Withers Moore said that while other European nations had recruited their Governments from time to time from the medical profession, hitherto medical men had been conspicuous for their absence from the ranks of the English Government.

Sir Richard Owen continues in about the same condition.

There is, as yet, no diminution in the metropolitan epidemic of scarlet fever.

London, November 5, 1892.

At the last meeting of the Medical Society of London, Dr. Richardson described a new method of physical examination under the name of "Intra-thoracic Auscultation." Some months ago a patient consulted him who was suffering from symptoms which obscurely suggested œsophageal disease. Considerable improvement took place for a time under dietetic and medicinal treatment, but after some months the symptoms recurred in a more severe form. He tried what he had termed the water-gurgle test for the diagnosis of stricture of the œsophagus; viz., he got the patient to attempt to swallow fluid, while he auscultated in the line of the œsophagus in front and behind. This gave negative results, so he employed the œsophageal tube. There was no serious obstruction to the passage of this at any part, but he thought he experienced some slight sense of friction. While examining, an idea which he had had once before, but had not acted on, suddenly occurred to him. Why not auscultate through the exploring tube? He at once sliced off a portion of the free end of the tube obliquely, slipped over this sliced end the terminal part of the double stethoscope, and thus made the exploring tube a continuous stethoscope. The results were most interesting and satisfactory. He could hear soft friction of the tube against the walls of the œsophagus, and was able to satisfy himself that the friction was uniform throughout, and that there was no stricture. On passing the tube into the cavity of the stomach he obtained a quite new sound, viz., a sound like a gentle seething as of air or gas agitated in a thickish fluid, and at times a gurgling sound of gas with another sound probably due to muscular contraction of the stomach itself. As the patient was not inconvenienced he withdrew the tube leisurely, noting the sounds heard meanwhile. The tube had only two openings in it, and these at the extreme end. On withdrawing the tube until the opening on the left side came in contact with that portion of the œsophagus which lay in immediate contact with the heart, he was able to hear both sounds as distinctly as those from a normal heart, though on previous ordinary auscultation he had failed to detect clearly the cardiac sounds owing to the heart's action being very feeble. The cardiac sounds thus heard, however, were duller in character than those heard through the chest-wall. Dr. Richardson suggested that this might be from a want of the resonance probably produced by the pleura stretched over the thoracic cavity. The sounds were, though, both loud and distinct. By moving the tube gently up and down he could get the second sound separately from the first, and *vice versa*. When the opening of the tube was midway so as to compass both sounds, there was not so much difference between the two sounds as was observable in ordinary auscultation. These modifications corresponded precisely with what he had learned many years ago when, with the late Drs. Baly and Sibson, he had seen Dr. Halford demonstrate Brien's theory of the cause of the two sounds. They then listened directly to the sounds from an opening in the chest-wall of an animal under anæsthesia, and found that with such immediate auscultation the sounds were deficient in sharp resonance, and more equable in tone than in ordinary auscultation. The same was the case in intra-thoracic auscultation. He expected, on withdrawing the tube further out of the œsophagus, that it would be possible to hear a loud sibilant or vesicular murmur in respiration, but it was impossible to catch a murmur, even on a deep inspiration, so distinct as the murmur heard from the chest-wall outside. The author suggested that the method he had employed might be found useful in the diagnosis of various conditions. He had found it of service in suspected œsophageal disease; it might also be of use in examining the stomach. Stricture of the œsophagus arising from aneurismal pressure would be instantly diagnosed, as we should hear the pulsation at the stricture. In heart disease it should enable us to distinguish between dilatation and hypertrophy. The diagnosis of clot on the right side might be made clear, and the differential diagnosis of right or left valvular disease ought to be rendered absolute when we had learned sufficient of œsophageal auscultation to discover the new distinctions of sound that would have to be made in some cases, at least, between the tone of the first and the second sounds, and had defined all new lines of distinction between those sounds as heard from within and from without the chest-walls. The clearest definition by this test should be obtainable between pericardial and endocardial friction-sounds and between pericardial and pleural friction.

Dr. Richardson remarked that as his communication was only a preliminary note he would leave untouched the subject of pulmonary auscultation by the intra-thoracic method, and also that of pharyngeal exploration. He then referred briefly to the limitations of the plan and the objections that might be taken to it. The question as to the modes in which the method might be improved by mechanical means opened up a wide field of inquiry. Up to the present he had found nothing better than a good-sized flexible tube with a large lateral aperture at the extreme end. Apertures were essential for the conduction of sound.

Mr. Alban Doran read notes of a case of an unusually large cyst of the vulvo-vaginal or Cowper's gland which

he had treated successfully by excision. Most of these forms of labial cyst, he said, were curable by partial operations, but these proceedings were often unsatisfactory in cases of cyst of Cowper's gland. A sinus was not rarely left behind, and this was as great a nuisance as the cyst itself. Extirpation cured the disease altogether.

At the last meeting of the Clinical Society Mr. Arbuthnot Lane read a paper, illustrated by two cases, in which he described a new operation ("Complete Erasion of the Ankle-joint") by means of which the ankle-joint could be fully exposed and every particle of its synovial membrane removed if necessary. A more or less horizontal incision was made from the anterior margin of the internal malleolus, outward, across the front of the ankle joint, backward immediately below the external malleolus, and inward above the heel to a point over the tendon of the flexor longus hallucis, everything being divided down to the bone. The only structures about the joint not cut through were the internal lateral ligament, the tendons of the tibialis posticus, flexor longus digitorum, and the flexor longus hallucis, the posterior tibial vessels, nerve, and the superjacent connective tissue and skin. On adducting the foot, any portion of the interior of the ankle-joint was fully exposed, and the narrow prolongation of synovial membrane which ran up between the tibia and fibula could be examined and dissected out by cutting through the inferior interosseous and the anterior inferior tibio fibular ligaments. Should the disease have extended to the subastragaloid articulation, it was necessary to divide all the structures covering in this joint superiorly and externally, together with the interosseous ligament connecting those bones, and in extensive disease of the astragalus that bone might be excised with advantage. Whether the cut surfaces of the several tendons were sutured together or not seemed to affect the subsequent utility of the foot but little, if at all. Some care, however, was necessary in putting the foot up in plaster bandages after the operation that the fibula did not drop back a little off its facet on the astragalus.

The customary annual meeting of the Fellows and Members of the Royal College of Surgeons took place at the College of Surgeons on Thursday last. The attendance was not large. The President (Mr. Bryant) gave a short address, in the course of which he pointed out that the report contained a humorous mistake. It stated that the council had had under their consideration two cases of misconduct by "members of the Council," in which they had inflicted the penalty of removal. The statement should read "members of the College." The proceedings somewhat resembled those at former similar gatherings. Mr. Tait moved a resolution to the effect that the report presented was ineffective and incomplete. In moving this, he referred particularly to the absence of any reference to the new university. The resolution was lost, but another resolution was carried calling for a cessation of the hostile attitude of the Council. It was also resolved that it was absolutely essential for the welfare of the College that the Fellows and Members should be consulted before any change was made in the constitution of the College, or before the College was committed to any extraordinary expenditure.

Medical Education of Women in Russia.—The establishment in Russia of a separate school of medicine for women which many people had hoped would soon be an accomplished fact has been postponed probably for an indefinite period. It is stated that the project has been set aside through the influence of the Minister of religion, who views the higher education of women in anything but a favorable light, being persuaded that the study of medicine leads to materialism and nihilism.

Professor Virchow, during his recent visit to Moscow, received the Russian Order of Stanislas First Class and the Grand Cross of the Swedish Order of the North Star.

OUR BERLIN LETTER.

(From our Special Correspondent.)

THE THERAPEUTICS OF CHOLERA ACCORDING TO THE EXPERIENCE GAINED DURING THE HAMBURG EPIDEMIC—DIAGNOSTIC AND PATHOGNOSTIC SYMPTOMS OF CHOLERA—THE IMMUNITY ACTIVITY AGAINST CHOLERA ASIATICA—BILLROTH'S TWENTY-FIFTH PROFESSORSHIP ANNIVERSARY AND JUBILEE—EXTRACTS OF VIRCHOW'S SPEECH WHILE ASSUMING THE DUTIES OF THE RECTORATE OF THE BERLIN UNIVERSITY.

BERLIN, October 22, 1892.

Now that the cholera is almost extinct in Germany we are looking over the different methods of treatment in order that we may accept the most approved. In the beginning all physicians recognized the "antiseptic doctrine," which was given the most thorough trial. To give a *résumé* of all antiseptic treatments would be to say—that all failed! In this category were included salol and benzo-naphthol, creosote and creoline, and also lysol. The same fate befell them all.

All Hamburg physicians unanimously declare calomel to be the sovereign remedy (in doses of $\frac{1}{3}$ to 1 grain). But calomel has its drawbacks, for although stomatitis can easily be prevented, nevertheless several cases of mercurial poisoning could be detected in the kidneys and in the intestines. Along with the calomel we hear great success attained with the ordinary physiological table-salt (Na Cl) solution.

As to whether subcutaneous or intra-venous applications is the better, is still a question of opinion. Among prominent Hamburg physicians, Professor Rumpf and Dr. Schede (surgeon) are in favor of the intra-venous treatment, whereas Dr. Lauenstein (surgeon), Dr. Michael, among others, believe in subcutaneous treatment. Dr. Guttman (Director of Moabit Barracks, in Berlin) discards the intra-venous injections as too bothersome and too complicated for the ordinary practitioner, and recommends the subcutaneous method; inasmuch as it can be applied to different parts of the body, whereas in the intra-venous method the places for application are limited. If the results and statistics show the subcutaneous method equal to the intra venous, then the former (subcutaneous) will be the method of the future, requiring the least technique and time.

Along with infusions and the calomel treatment in the stages of cholera intoxication, "the hot bath" is mentioned for the subnormal body temperature, to be repeated at stated intervals. Combined with the above are hot coffee and tea, wine, champagne, and injections of camphor-oil. The pains in the epigastrium and calves of legs were best relieved by hypodermics of morphia. In the stadium algidum, the above-named remedies were used along with vapor baths, inhalations of nitrate of amyl, to dilate the contracted arteries and increase the circulation. With the exception of camphor injections and morphine, all the above-named remedies proved useless and were discarded. An important point to mention is the opium treatment, which proved to be a fiasco, and was mentioned by all Hamburg physicians to be decidedly injurious. Just as our therapeutic so our diagnostic experience has through numerous observations somewhat increased. We need only refer to an interesting paper of Dr. P. Guttman, read about two weeks ago before the Society of Internal Medicine.

Dr. Guttman says the severe cases are easily made out; the mild cases are hard to diagnosticate. Without a bacteriological examination, impossible in the severe cases, the asphyxia picture is so characteristic that a different affection cannot be mentioned. But this observer mentions an antipyrin poisoning which showed great similarity with cholera, excepting there was hard, solid fecal discharges. Besides, the speaker mentions two cases having nothing but a mild form of diarrhœa and good constitutional condition. In all these the bacteriological examination proved the existence of a mild

but real form of Asiatic cholera. Guttman further tested how long the comma bacilli can live and develop during the course of the disease, and found in a mild case five days, in two cases seven days, two cases eight days, two cases nine days, and one case ten days.

In a case that died on the eighth day the bacilli were easily cultivated from the intestine post-mortem. Along with these therapeutic and diagnostic investigations, the immunity experiments run parallel; although practically useless, they still point the way in which immunity shall render us proof against cholera infection in the future. Two important contributions should be mentioned in this connection: one from Dr. Klemperer, who states that a patient convalescing from cholera is proof against other infections, and besides, his serum can render others immune against infection. It was next found that the serum of non-infected persons contains a certain antitoxic property which could be transferred to guinea-pigs. Klemperer produced a prophylactic vaccination against cholera by taking a three days old culture of comma bacilli, heating them two hours to 70° C., and injecting these in increasing doses subcutaneously. After injecting 3.6 c.c. of such a culture. 0.25 c.c. of serum drawn off through arterial bleeding could render a guinea-pig immune against cholera poison. It is, therefore, proven that the person experimented with is also cholera-proof. The author further found, the same as Koch and his followers, that cholera bacilli injected under the skin will produce mild inflammations with constitutional disturbance.

Klemperer injected a number of young physicians with small quantities of fresh virulent cultures under the hand, and found that the subcutaneous injections produced no mentionable disturbance.

In the subcutaneous connective tissue the bacilli die quickly. The serum of such patients protected a guinea-pig from the deadly dose after an injection of 0.5 to 1 c.c. The author aims at effecting immunity in the same way as nature, without danger. If the latter investigations by Klemperer are not all that we aim at, then a paper recently written by Dr. A. Lazerus, assistant at the Moabit Hospital, and published in the last number of the *Berliner Klinische Wochenschrift*, is a decided advance. The author took the blood serum of convalescents from cholera and injected it into guinea-pigs, to prove that they were immune against cholera. In every case taken for experiment the comma bacillus had been previously demonstrated. It was then shown that the blood-serum of persons who had just had cholera asiatica possessed an enormous preventive power against cholera intoxication. The smallest preventive dose was found to be 0.0001 (one decimilligramme of serum). This dose was found not only to prevent disease, but to prevent death.

On October 15th Professor Billroth celebrated his twenty-fifth professorship anniversary in Vienna. His numerous students and assistants, most of whom have to-day the most prominent surgical chairs in Europe, presented him with a Surgical Jubilee Number, through Czerny, of Heidelberg, the oldest assistant of Billroth.

Professor Albert, of Vienna, was toast-master. He mentioned the difficulties which the Chair of Surgery demanded in 1867, requiring a man well up in practical medicine, in physiological, and pathological anatomy, one who could be a teacher, a writer, and an operator. These qualities were found in Billroth, who has made the University a new surgical school. Billroth, in answering, mentioned his teachers, W. Baum and B. von Langenbeck, whose traditions he had accepted, and which he had always tried to teach his students. The same day that the Billroth festivities were held, Virchow accepted the rectorate of the Berlin University. He had to wait a long time for this honor, which had been given to numerous younger and lesser lights. But since the faculty elevated Virchow to be their sector magnificus, they have honored themselves.

His speech of acceptance was entitled "Teaching and Learning," which is now in print.

In this speech he cites the belief of celebrated pathologists in the methods of teaching and learning of to-day. Both are strongly criticised. He states "that disputed questions between scientific men should not be mentioned in the course of instructions in universities, and should be excluded therefrom."

But we can demand that a young man who has a good thinking capacity can accept without danger the results of astronomical and biological observations. He does not need mathematics in order to study the movements of the heavenly bodies. Physics is now a mathematical science. Chemistry and physiology are more and more based upon calculations. But not only counting but thinking is necessary to understand.

In many schools it is believed that when a logical sentence is cited here and there that justice has been done to logic. How is it possible that a person who does not know the laws of thinking can devote himself to physiology? How can the twisted relationship of mental be equal to a bodily existence.

And now to natural sciences. What satisfactory objects for learning and teaching are found in the natural sciences, botany, geology, minerology? It is a misunderstanding to think that the university teacher lays stress on systematic knowledge gained systematically; it is easy to teach in a university, but the real school depends on the interest infused with the aid of bodily sympathy.

We now have to lament that a great many of our students have no real knowledge of colors. That they cannot differentiate the consistency of the upper layer of objects. We all hope that the words of the great scientist, of which the above is an extract, will be echoed over the world.

New Instruments.

ACCESSORY SINUS IRRIGATION TUBES.

By ROBERT C. MYLES, M.D.,

NEW YORK.

SURGEON, THROAT AND NOSE DEPARTMENT, CHURCH HOSPITAL AND DISPENSARY; ASSISTANT SURGEON, NOSE, THROAT, AND EAR DEPARTMENT, NEW AMSTERDAM EYE AND EAR HOSPITAL; LECTURER ON DISEASES, AND DEMONSTRATOR OF ANATOMY, OF THE NOSE AND THROAT, NEW YORK POLYCLINIC.

I PRESENT an instrument which has served me so well in a practical sense, that I feel justified in advocating its use by the profession, for the purposes hereafter mentioned. It consists of a pure silver tube about four and one-half inches long, with one end bulbous for inserting into a rubber tube. The other or distal end is slightly longer than the body of the tube, and rounded to prevent laceration of mucous membrane when being used. It should be procured in sets of three or four different sizes, ranging from as small a size as can be made from reliable specifications, and which will permit of a flow of fluid little larger than that of an ordinary hypodermic syringe, to one which has a canal about the calibre of a No. 22 platinum wire. The tubes can be bent into almost any shape desired, and can, in the majority of cases, be readily and easily introduced into the antrum of Highmore, by anyone who has an accurate knowledge of the hiatus semilunaris, with very little pain and inconvenience to the patient. When bending the tubes great care should be observed that it be done around some circular surface, such as the finger, as abrupt bending often breaks them. As to the success of introducing them readily, much will depend upon whether the septum is deflected superiorly, the size, position, and firmness of middle turbinated body, and abnormalities of foramens due to degenerative inflammatory processes and adhesions. To succeed, notwithstanding these impediments, cocaine should be carefully applied to the limited areas. The different size tubes should be applied, bending them respectively with cir-

cle curve, $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$, and 1 inch from the distal end. Then, to find the antrum of Highmore opening, pass the tube forward along the outer wall of the space beneath the middle turbinated body, commencing about the middle third of the same. If not successful, commence beneath the anterior end of the middle turbinated body, fishing, as it were, along the outer wall beneath and external to the bulba ethmoidalis. Following this wider valve-like lip of the hiatus upward and outward, the tube will enter the infundibulum, and this is in the space beneath the attachment of the anterior end of the middle turbinated body. A rubber tube with double layers at each end should go with each tube or set, to be used for attaching the same to a proper syringe. I use them frequently for washing out the frontal sinus by the nostril, but in these cases often have to remove a part of the anterior end of the middle turbinated bone, and sometimes curette the infundibulum. I have found them useful in treating empyema of the ethmoid cells, but usually through an artificial opening in the roof of the space beneath the middle turbinated body. The results have been brilliant in acute cases of catarrhal or grippe origin; in subacute cases relief has been obtained in all, and a cure in the majority of cases. In the chronic cases with pyogenic membrane, granulation, and polyp tissue, in which operations have been refused or deferred, washing out with different medicated fluids has produced marked improvement in the general symptoms, with pleasant temporary relief in the local ones. Notwithstanding some adverse criticism of this procedure, I have demonstrated its practical utility to the class of students at the New York Polyclinic on various occasions, and in as many as four different cases in one evening. The tubes were made by E. B. Meyrowitz, of New York.

25 West Thirty sixth Street.

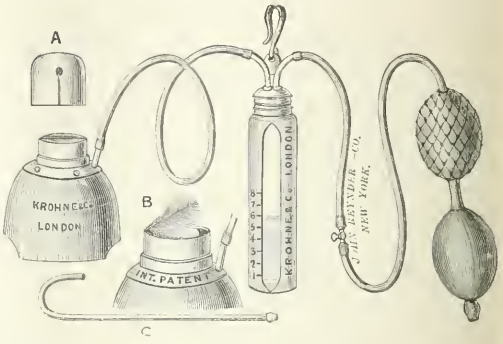
A NEW FEATURE OF ANÆSTHETIC INHALERS.

The following conclusions of the Hyderabad Chloroform Commission are offered for what they may be considered to be worth: 1. That the administration of chloroform is free from risk if the breathing is perfectly regular throughout, and the inhalation is stopped as soon as the patient is fully under its influence. 2. That death from chloroform is always the result of an overdose. 3. That chloroform never causes death by sudden stoppage of the heart. 4. That there is not such a thing as "chloroform syncope;" and that in death from an overdose of chloroform the respiration always fails before the circulation. 5. That the heart is the very last organ to give in under the action of chloroform. 6. That it has demonstrated beyond contravention that, with proper attention to the breathing, chloroform can be administered with safety in any part of the world.

Based on the foregoing data, Messrs. Krohne & Sesemann have devised a respiration indicator, applicable to all varieties of anæsthetic inhalers, whereby the nature, frequency, and character of the respirations of the anæsthetized are shown, so that, owing to the respiration being thus under constant observation, all danger of syncope, coma, or other failure of the heart's action, due to an overdose or a prolonged influence of the drug administered, is removed, as immediately upon indication of an abnormal sign by certain premonitory symptoms affecting the respiration, or by a slowing or entire stoppage of the latter, the apparatus can be withdrawn at once from the patient, and artificial respiration or other recuperative measures resorted to in time to avoid accidents.

The figure shows the improved Junker's inhaler, with the feather indicator, *B*, showing the same. The feather moves by hinge up and down in accordance with the respiratory movements. One complete compression of the bellows will force 5.19 cubic inches of fresh air into the bottle, and escape with an impregnation of a minim of chloroform to the mouth-piece to be inhaled. For operations in the mouth, face, nose, or eyes, a pliable metal tube is supplied, whereby anæsthesia can be maintained through the mouth or nose.

The advantages of this apparatus are: A continually fresh supply of impregnated air, exhaled air not being



breathed over again; the patient does not breathe through the apparatus; twenty to twenty-five compressions per minute will supply the requisite amount of narcotic vapor, and the additional amount of air required to fill the lungs (20 to 30 cubic inches) enters freely at the respiration indicator. The administrator has complete control over the anæsthetic. Economy of anæsthetic fluid.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 5, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	35	7
Scarlet fever	85	10
Cerebro-spinal meningitis	1	2
Measles	60	3
Diphtheria	108	30
Small-pox	5	6
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Medical Students in German Universities.—In the twenty universities of the German empire the medical students for last summer numbered 8,838. These were distributed among the various universities as follows: Berlin, 1,185; Bonn, 325; Breslau, 292; Erlangen, 424; Freiburg, 481; Giessen, 172; Gottingen, 200; Greifswald, 393; Halle, 283; Heidelberg, 278; Jena, 212; Kiel, 335; Konigsberg, 255; Leipzig, 834; Marburg, 266; Munich, 1,443; Rostock, 138; Strassburg, 333; Tübingen, 230; Würzburg, 743.

Carrier-pigeons and Vaccination.—At the last meeting of the Academie de Medicine, Dr. Hervieux read a report by an army surgeon, M. Stroebel, on the transport of vaccine by carrier-pigeons. It appears that one pigeon is capable of conveying in one journey from five to six tubes. The utility of this means of transport in times of war is very obvious, and one can imagine the joy of the representatives of the Army Medical Department at the apparition of a flock of these swift vaccine carriers in a besieged town.—*Annals of Hygiene.*

THE RESULTS OF EXPECTANT TREATMENT IN THREE HUNDRED AND TWENTY-THREE CASES OF TYPHOID FEVER.

BY ARNOT SPENCE, M.D.,

NEW YORK.

THE treatment of typhoid fever has always been an interesting subject for discussion. Even now some contend that the disease requires a great deal of treatment, while others assert that the best results have been obtained by the expectant plan.

It can be from no lack of material that the better method remains undecided; for, notwithstanding the many advances in sanitary science, and the constant attention given to this disease by our Municipal Board of Health, typhoid fever still prevails to some extent in New York City.

During the year 1891, 1,342 cases were reported to the Bureau of Contagious Diseases; and it may be safely said, even though the Health Department endeavors to enforce a system of reporting infectious diseases, this number will fall far short of the actual cases existing during that time. Of the cases, 384 were deaths, over 28.6 per cent. of those reported. This disease is met with, it is true, in private as well as hospital practice, but the large number coming under the observation of one man in the hospital makes such records obviously of greater value. Again, the results of hospital treatment are very much better, owing to the almost continuous attention of the physician, and the intelligence as well as the strictness of the experienced nurse. In the cases of private patients, the sympathizing and willing friend is the greatest enemy of the doctor and the nurse, and consequently the ever present obstacle to good results.

St. Francis Hospital of New York City treats, relatively speaking, a large number of cases of typhoid fever each year; and during the last thirteen years there were treated in that hospital 1,012 cases, with only 162 deaths, a mortality of sixteen per cent. The cases forming the subject of this report, 323 in number, include all those admitted to the service of Dr. J. H. Ripley, from October 1, 1884, to January 1, 1892, and most of them came under the observation of the writer. Of the 323 cases, 47 died, a gross mortality of 14.23 per cent. These 47 deaths included 12 moribund cases, or such as were, on admission, so weak that they died within forty-eight hours. If we then omit these moribund cases, as in fairness we can, the death-rate is reduced to 11.25 per cent.

The cases of this report were all real cases of typhoid fever; for the list does not contain any so-called "aborted cases," simple febricular, or any in which typhoid fever was only suspected for a few days. The diagnosis was as certain as we can ever make it, in each and every case. In those cases that died after admission in a moribund state an autopsy was performed to clear up any doubt.

A few words will suffice to explain the treatment employed. It was purely expectant. The drugs used, consisted of a 5- or 10-grain dose of calomel to begin with, if the disease was not too far advanced; whiskey, when stimulation was necessary, and in the case of very great and continued pyrexia (over 105° F.), the cold pack was the usual means employed to reduce it. When possible the water-bed was used in these high temperature cases, but only occasionally was antifebrin or phenacetin given, and then only in single doses. There is no doubt but that the value of antipyretic drugs in all febrile diseases is over-estimated; and where the patient is fortunate enough to survive their use, he is very seldom, if ever, benefited by them. Troublesome diarrhœa was treated with bismuth combined with small doses of opium; or if very obstinate, 5 grain doses of naphthalin were given every two hours until relief was obtained. For intestinal hemorrhage, laudanum in 5- or 10 drop doses was administered at short intervals until the desired effect was secured.

The nursing, which is of such moment in this disease, was most strictly attended to by the sisters in charge of the hospital. The diet was wholly a fluid one, consisting in the most part of milk, together with strained meat broths, and was so maintained until a full week of normal temperature had passed. Even then great care was taken, and the full diet only reached in a gradual manner. The patient, as a matter of course, was kept in a reclining posture and was not allowed to rise or leave the bed under any circumstances.

The cases here reported were mostly drawn from the East Side tenement district, and were therefore, principally of Austrian, German, or Irish nationality or extraction. They came from the lower walks of life, being hard worked, poorly nourished, living under bad hygienic surroundings, and consequently in no physical condition to withstand a tedious and exhausting disease. Again, thrifty and independent as a class—also very superstitious—they use the hospital only as a place of last resource, and cause us to combat in addition to the other drawbacks, the great dangers arising from delayed admission and poor previous care. Only on rare occasions do these people apply for admission before the end of the first week of the disease, and as a rule, not before fourteen days or more of illness. We have, as I have previously mentioned, a number admitted in a moribund condition; this condition, often due to intestinal hemorrhages or intestinal perforation, forces them to apply for admission against their own wishes.

Causes of Death.—The causes producing death in the 47 fatal cases have been classified, and were as follows:

Cause.	Male.	Female.	Totals.
Moribund on admission	7	1	8
Moribund, with intestinal perforation and peritonitis	1	..	1
Moribund, with intestinal hemorrhages	1	..	1
Moribund, with lobar pneumonia	2	..	2
Intestinal hemorrhages	2	1	3
Intestinal hemorrhages and lobar pneumonia	..	1	1
Intestinal perforation	2	..	2
Intestinal perforation and peritonitis	2	..	2
Intestinal hemorrhages, perforation, and peritonitis	1	..	1
Relapse	1	..	1
Typhoid, with pharyngeal diphtheria	..	1	1
Typhoid, with pneumonia	1	1	2
Typhoid poison and exhaustion	15	7	22
Totals	35	12	47

Only 22 of all the deaths were due to the typhoid poison alone, being about one-half, or more exactly, 6.8 per cent. of the total number of cases. Of the other 25

fatal cases, 11 succumbed to the intestinal lesions, which it may be safely assumed cannot be prevented, and are seldom passed over without a fatal issue. Pneumonia caused death in 4 of the cases, 2 of these being moribund when brought to the hospital. One death occurred as a result of the rare complication, pharyngeal diphtheria, and one during a relapse. In another of these fatal cases, to be further explained later on, an intestinal perforation occurred during a relapse, but the case has been included in the intestinal class.

Now, omitting 2 of the 12 moribund cases, these 2 having died of the intestinal lesions, 10 still remain whose deaths may be put down as due to neglect; or speaking mildly, their lives were shortened by being moved while in such a precarious state.

Tabulating the cases as they occurred so as to show the results of each year's work, we have the following:

Year.	Number of cases.	Number of recoveries.	Number of deaths.	Number of moribund cases.	Deaths from intestinal lesions.	Percentage of deaths.	Percentage after deducting moribunds.
From Oct. 1, 1884, to Jan. 1, 1885	33	28	5	1	2	15.1	12.5
During 1885	43	38	5	3	1	11.6	5.0
During 1886	41	38	3	1	..	7.3	5.0
During 1887	42	34	8	1	3	19.0	17.0
During 1888	29	24	5	3	3	17.2	7.6
During 1889	58	46	12	2	..	20.6	17.8
During 1890	40	36	4	..	1	10.0	10.0
During 1891	37	32	5	1	1	13.5	11.1
Totals	323	276	47	12	11		

It will be noticed that the best result was obtained in 1886, when 41 cases were treated and only 3, or 7.3 per cent., died. No intestinal accident happened, and only 1 moribund case was admitted. Had that case remained away, the mortality would have been only five per cent. This same result, 5 per cent., was also reached in 1885 when we leave out the 3 moribund admissions.

In that year, 1885, 43 cases were treated, with 5 deaths, or 11.6 per cent.; 3 of these were admitted moribund, and 1 died of the intestinal lesions.

The highest death-rate occurred in 1889, when out of 58 cases 12, or 20.6 per cent. died; even after omitting the 2 cases that entered in a moribund state, we still had the high rate of 17.8 per cent.

Summing up the yearly results we had in 1889, 20 per cent. mortality; in 1887, 19 per cent.; in 1888, 17 per cent.; during the three months of 1884, 15 per cent.; in 1891, 13 per cent.; in 1885, 11 per cent.; in 1890, 10 per cent.; and in 1886, 7.3 per cent. These figures, it must be understood, show the results obtained, taking all cases into consideration, and are materially reduced when the cases admitted in a collapsed or moribund state are omitted, as is shown in the table.

The low rate of 7.3 per cent., reached in 1886, is that which Dr. Brand obtains, as shown in his reports of cases treated by his cold-bath plan. He says one cannot hope to reach a lower rate than 5 per cent., which mortality (5 per cent.) we were enabled in fact to obtain during two consecutive years. It may be mentioned here, for it tends to augment the value of the results we have obtained, that the subjects Dr. Brand had to treat were of an entirely different class physically from those we receive. They were as a rule robust, vigorous young soldiers, and not the poorly-fed results of competitive bread-winning found in this great city.

The number of deaths from the intestinal lesions it will be noticed, bears no fixed ratio to the number of cases in the several years' groups. The varying results obtained during these years, tends to show very plainly the great changes in its virulency that this disease assumes during different periods. One year all of the cases will be comparatively mild, and the next the poison may show its malignancy in the stupor, delirium, and other nervous manifestations of the so-called typhoid state.

In the following table the cases are divided into groups of one hundred; and in order to include the last, or odd 23 cases, a fourth group, composed of the last one hundred cases treated, has been added:

	Number of recoveries.	Number of deaths.	Number of cases moribund.	Number of deaths from intestinal lesions.	Mortality, omitting cases moribund, per cent.
First 100 cases	89	11	4	3	7.2
Second 100 cases	81	19	5	6	14.7
Third 100 cases	85	15	3	2	12.3
Last 100 cases	87	13	2	2	11.2

In the first 100 cases there were 89 recoveries and 11 deaths, including 4 admitted moribund; 3 cases died of the intestinal lesions. The death-rate, omitting the moribund cases, was 7.2 per cent. The second 100 gives us only 81 recoveries, with 19 deaths, 5 of those being "moribunds;" 6, a large number, died of the intestinal lesions, and the mortality-rate of this group, minus "moribunds," was 14.7 per cent. The third 100 gave 85 recoveries and 15 deaths, including, as usual, moribund cases, 3 in number; 2 deaths were caused by intestinal accidents, one of hemorrhages and one of perforation; and the death-rate, leaving out the cases admitted in collapse, was 12.3 per cent. The fourth series, which is composed of the last 100 cases, and which includes the odd 23, gave us 87 recoveries, while 13 cases were fatal, including 2 admitted moribund. Two of the patients succumbed to the intestinal lesions and the percentage obtained, after omitting the "moribunds," was 11.2. Even in groups of 100 cases the mortality-rates are variable, though not as markedly so as in the smaller sets. On arranging our cases however, in series of 200, we find the death-rate much more stable, it being between 14 and 15 per cent. These figures are reduced to 10 per cent. and 11 per cent. respectively when we take into consideration the cases that were admitted in collapse, and the mortality of the whole 323 cases to 11.25 per cent.

Age.—The patients ranged in age from eight to seventy-four years; of the former there were three cases, and at the latter age but one a female, who by the way, was discharged cured. The next oldest was fifty-seven years of age. The number of cases at the various ages were as follows:

Age.	Cases	Deaths.	Mortality.
			Per cent.
Under 10 years	4	1	25.0
From 10 to 15 years	8	1	12.5
From 15 to 20 years	67	5	7.4
From 20 to 25 years	104	13	12.5
From 25 to 30 years	84	13	15.4
From 30 to 35 years	27	3	11.1
From 35 to 40 years	17	7	41.1
From 40 to 45 years	6	3	50.0
From 45 to 50 years	3	1	33.3
At 50 years and over	3	0	0.0

This table shows that 255, or more than two-thirds of all the patients, were between fifteen and thirty years of age, and that 104, or nearly one-third, ranged from twenty to twenty-five years in age. The greatest mortality, 50 per cent., occurred in those patients that were between the ages of forty and forty-five; and, next to the last, in which there were no deaths, the smallest, 7.4 per cent., occurred in those between fifteen and twenty years. The groups however, are not sufficiently large, except in three instances, to make the ratings of much value.

The death happening in those under ten years, was that of a boy eight years of age, who was admitted on the fourteenth day of his sickness. The fever ran a favorable course until the twenty-sixth day, when a relapse occurred, and he died on the thirty-ninth day of the disease.

An autopsy revealed perforation of the gut at the site of a sloughing ulcer, also some recently healed Peyer's patches. The fatal case in the second set was that of a boy aged eleven, who, having been brought into the hospital in a moribund state with well-marked peritonitis, died within thirty-six hours. The autopsy showed a general suppurative peritonitis and perforation of a typhoid ulcer.

These deaths have been particularly mentioned, for the reason that the mortalities of twenty-five and twelve per cent., respectively, are rather high, considering the ages of the cases. It is generally believed that typhoid fever is, in children, rather more favorable as to prognosis than in adults.

Sex.—When these 323 cases are divided as to sex, we find that there were 251 males and 72 females. Among the males 35, or 13.9 per cent., died, and of the females 12, or 16.6 per cent., were fatal. Of the 12 moribund cases only one was of the gentler sex, and only two females died of the accidents liable to follow the intestinal lesions.

Season.—The greatest number of admissions of typhoid fever patients occurred during the autumn months, and the least number in the spring.

Spring	15	Autumn	203
Summer	87	Winter	18

Of the 87 cases admitted in the summer time, 14 died, or 16 per cent.; and of the 203 who entered in the fall 28, or 13.7 per cent., proved fatal. The marked difference in the number of the cases comprising these two seasons' admissions lessens the value of the relative mortality-rates. It is contended by some, that the death-rate is higher during the summer than during the cooler months, but a great many factors must be taken into consideration before agreeing to that opinion.

Complications.—In only about two per cent. of the cases did relapses or reinfection occur, and this very favorable showing is undoubtedly due to the strictness of the dietetic treatment and the nursing.

Pneumonia occurred as a complication in 15 of the cases, 10 being croupous and 5 catarrhal in form. Of the 5 fatal cases, all of which were of the croupous variety, two were admitted moribund and one had also intestinal hemorrhages. It will be noticed that recovery took place in all of the cases complicated by the catarrhal form of this disease.

Hemorrhages from the bowels complicated ten of the cases, and six of these ended fatally. In one of these fatal cases the hemorrhages were followed by a perforation of the gut, and later by suppurative peritonitis; in another, as has been mentioned, croupous pneumonia was an additional complication. Of the four cases ending in recovery one had profuse hemorrhages on four different occasions, and it was most certainly believed that he had a perforation of the gut also.

By no physical signs, or subjective or objective symptoms, can the physician diagnose the gravity of the intestinal lesions before the gut has suffered a perforation. Frequently at the autopsies have the ulcerations been found to have eaten clear through to the peritoneal covering of the intestines.

A number of our cases were also complicated by other diseases which were fortunately not fatal. They were as follows:

	Cases.
Fracture of the lower jaw	1
Ischio-rectal abscess	1
Phlebitis	2
Phthisis, incipient	3
Phthisis with Pott's disease	1
Pleurisy with effusion	2
Purulent otitis	4
Suppuration of a thyroid cyst	1
Varicose ulcer (large) of leg	1

That a very low mortality-rate can be reached in small, or, considering the tendency of this disease to a favorable termination, in relatively small series of cases, is particularly shown in the results achieved during 1885 and 1886, when 80 cases were treated, with only 5 per cent. of deaths. A number of such series might easily be collected, and when combined would, of course, result in a surprisingly low rate. Thus it is plain that a just and average mortality can only be obtained from the treatment of a large number of consecutive cases; those cases should be seen in one institution and be under the care of but one man, or a very few men, to insure a reliable report.

In conclusion we can say that of our cases nearly four per cent. died as the result of admission in a moribund state; that over three per cent. died of the accidents incidental to the intestinal lesions, as hemorrhages, perforation, and peritonitis; that 1.5 per cent. died of complicating pneumonia; that 6.8 per cent. died of the typhoid poison itself and its resulting exhaustion. That the death-rate was higher among the females than the males, and that the lowest mortality was in those cases of an age between fifteen and twenty years.

It is not likely that any treatment can be devised which will prevent absolutely such occurrences as intestinal hemorrhages and intestinal perforations, and therefore we shall always have those to contend against. A treatment which may possibly antidote the specific poison of typhoid fever without lowering the vitality of the patient will be, in accordance with our present theory, the one to reduce its mortality.

The writer wishes to express his grateful thanks to Dr. J. H. Ripley for the permission given to report these cases, and for his helpful suggestions and kind advice.

70 West Seventy-first Street.

SOME OBSERVATIONS ON THE ETIOLOGY AND TREATMENT OF DIPHTHERIA.

By SURGEON C. A. SIEGFRIED, U.S.N.

United States Naval Training Station, Newport, R. I.

Within a short period the profession has been put in possession of a relatively important advance in the etiology and treatment of this dreaded disease; and by the combined labors of the bacteriologists and pathologists and the clinicians, in line with the long-continued researches on anthrax, tubercle, the pus organisms, and the chain cocci, the diplococcus of pneumonia, tetanus, and some others not so well distinguished by corroborative evidence, it is hoped that we are now coming to a sound and fruitful appreciation of the etiology, and an increasingly successful management, of the "diphtheritic process." As with anthrax, it has required many years and many investigators to arrive at the present stage of what may be fairly called brilliant and successful studies regarding the disease diphtheria, its separation from the common membranous sore throats, and some accurate knowledge of its virulent and destructive agency on nervous tissues. Starting from Klebs's discovery of the bacillus in 1873, and Löffler's success in first isolating and producing pure cultures of it, one by one the clouds of empiricism have given way to the successive steps, until now it seems to be confirmed beyond reasonable doubt that this organism is the sole originating cause of diphtheria, that it can be found in the superficial layers of the membrane in most cases of the disease, and that it elaborates, in its growth, an infective principle which, being absorbed by the circulation, sets free a ferment having the power of decomposing or digesting certain proteids in the body, forming albumoses and an organic acid. These digested products are the toxic agents, cause fever, depression, and the characteristic degenerations of the component nerve-structures, as, for instance, the gradual disappearance of the white substance of Schwann, and rupture of the axis cylinder in peripheral motor-nerves, and various degenerations of sensory and sympathetic nervous tissues—described at length by Martin, Dejerine, and others.

The diphtheria bacillus is not found, thus far, in the

general circulation or in the body at large, and it is not reasonable to expect to find it so distributed, from the nature of its toxic products; but it is found in the early hours of the disease in the top layers of the membrane, as described below. The virulent chemical agent or ferment, first separated from pure cultures by Roux and Yersin (who also first produced the characteristic paralysis in animals by inoculations with it), and confirmed by Brieger and Fränkel, was found capable of killing, in the dose of 0.0004 gramme, two rabbits weighing three kilogrammes each. It is considered to be a ferment from its power of prolonged effect on the body, lasting over several days, and from the fact that heating attenuates the poison, and boiling destroys it. The physiological action of the albumoses (there are three made out by Martin) obtained from artificial cultivations of the bacillus in one to two per cent. solutions of alkali albumin in beef-broth, without the addition of peptone, when injected into animals, is similar in its effects to the well-known phenomena observed in man with typical diphtheria, such as fever, depression, loss of weight, diarrhœa, dyspnœa, and a progressive paralysis of the muscles dependent on a parenchymatous degeneration of the peripheral and other nervous structures. Owing to the peripheral degeneration of the phrenic nerve it is uncertain how far the respiratory attacks are dependent on this degeneration, and how much they are due to an effect on the central nervous system.

The diphtheria products are special nerve-poisons, and they may cause degenerative changes of nerves even during short periods of the acute disease; they have been likened in their effects to snake venom, and still more so to the poisonous proteids existing in jequirity seeds. The organic acid, the other substance found as one of the diphtheria products, has an insignificant but slightly similar action on the animals experimented with, and they recovered; yet when afterward killed, they had also some degree of fatty degeneration of the heart-muscle, and degenerations of the phrenic nerve.

The anthrax bacillus produces toxic albumoses and an organic *base*, and that organism is found, in the first few days of infection, mainly in the spleen and liver; then, following the conquest of the blood- and tissue-cells—the intoxication—it is found swarming in the body at large, the final fatal product being an alkaloid. In diphtheria these albumoses are found to be of far more virulent capabilities, the organism, as a rule, early disappearing from the membrane and its localized seats, and it has not been found distributed in the body. The peculiarities and properties of the secondary infective agent of the latter bacillus suggests a diastatic ferment, and the albumoses are the actively fatal agents. These "albumoses of diphtheria cannot be distinguished from those of anthrax or of peptic digestion, by chemical means. Their physiological effect—a test far more delicate than any chemical reaction—is the only method by which their specificity is made evident." Not all albumoses produce fever, that from tetanus, for instance, producing depression of temperature, and that from diphtheria, in medium dose, has the same effect. The proteids, always existing in relatively large amounts in the spleen, are the main source of the digested products, the albumoses, resulting from the action of the ferment elaborated by the diphtheria bacillus in the membrane. The fibrin of this membrane is the earliest partly digested product of the bacillus, and this structure may in turn serve as culture media for other micro-organisms, which in turn overcome and finally destroy the original Löffler bacillus. The fundamental facts regarding the chemico-physiological action of anthrax and diphtheria products so far worked out, have been and are suggestive of definite lines of procedure regarding the micro-organism of rabies; and with tetanus are now producing practical results. It is also justifiable to place the toxic principles of the tetanus and rabic organisms—although the latter is not yet known—in the same category with diphtheria, their effects and the phenomena in the body being presumptive of their being virulent nerve-poisons, the primary infective agents being in small amount which, when absorbed, act with prolonged decomposing effect on certain proteids, with power of selecting the components of central nerve-structures.

Bearing these facts in mind, it becomes apparent with what importance the diagnosis should be made at as early a period as is possible, when one has to do with membranous disease of the air-passages and throat, and the character of the means and methods to be applied in the treatment. It is needless to say that not all membranous throats are diphtheritic, for they are not; yet it is common to hear of considerable diphtheria, diphtheroid, and contagious throat disease, and there is very much uncertainty in the minds of medical men how otherwise to name many of these complex cases under the circumstances; the treatment being much the same, and the common welfare bearing on the matter in a serious and complicated way. As a matter of fact, probably not over twenty per cent. of the cases reported are in reality diphtheria, and it only requires some courageous patient, whose business and household have been in part ruined, to bring suit against some city authorities for the destruction they have wrought him, because he has gone through an ulcerated throat with membrane, and has been reported and labelled as being an object to be shunned for weeks by his neighbors. If such patient brought his suit for damages against a health authority and city, and could prove that no accurate diagnosis was obtained, that he promptly recovered with no ill-effects following, it is quite likely that a body of well informed practitioners, in any of our large cities, would testify that he probably did not have diphtheria. In such a case he, in equity, should be reimbursed by the same powers that came down upon him, labelled him as diphtheria, and wrought upon him and his home the wonderful performance of a sulphur fumigation and the usual "taboo" in such cases. Now, it would seem that in justice, before proceeding thus far, it would be the duty of the physician in attendance, or the health authority, to procure this diagnosis if it is possible to do so, and that it is not nearly so difficult as it would appear, is mainly the object of this communication.

Eminent and widely known practitioners have recently stated that there are cases of diphtheria in which no means known to them have had the slightest curative effect. This is undoubtedly the fact, but it is explicable when it is known that flecks of membrane exist in concealed localities, or that cannot be reached by ordinary means; or, before being reached and treated, have already been the seat of well-developed colonies of the bacillus with consequent results. And, finally, individual impressibility to the toxic products varies enormously. The organism grows rapidly, colonies becoming visible, in blood-serum and glycerined agar culture media, in from twelve to thirty-six hours. The method of procuring small portions of the membrane and transferring them to the culture-tubes or dishes, and keeping them in incubators at about blood temperature, is obvious. If enough plants are made and the proper care is observed, the diagnosis can be made by the following day, in all probability. Long forceps and scissors duly sterilized are used to procure bits of membranes from the parts that can be reached, or a detached portion may be treated in some solution, and an underlying section gotten for planting. Baginsky,[1] after securing a bit of membrane, dips it for a moment or two in a two per cent. boric acid solution, believing that thus the common mouth-organisms are retarded or destroyed, and then places it in blood-serum tubes. He reports finding the Löffler bacillus in 118 instances out of 154 cases, and as early as ten hours after getting the membrane for culture. Of these, 39 were paralyzed in more or less degree, 17 went to septic infection, 44 were tracheotomized, and 29 were without any complications. In some cases the bacillus was not found, yet they had all the symptoms of the disease; four

[1] Deutsche Med. Woch., No. 6, 1892.

proved fatal, one was already paralyzed on its reception to hospital, a second was complicated with measles and died of pneumonia, and two of septic involvement, double empyemia, etc. Some of the cases showed, instead of the Löffler bacillus, the chain cocci, or streptococci, and ran a malignant course mainly, however, of septic character, and not in the line of true diphtheria. Baginsky in his paper speaks of two forms of membranous throat disease, one the true diphtheritic process, the other a relatively less serious disease and not transmissible, and hence the necessity of culture-tests and scientific diagnosis. He notes two cases of rhinitis fibrinosa, or "chronic diphtheria," which recovered, the bacillus obtained from the membrane, cultivated and injected into rabbits, killing them with all the symptoms of the disease, including the paralysis. The membranous throats of scarlatina gave only streptococci, and he thinks that further studies of such cases might throw light on the scarlatinal etiology. Henoch recommends anti-diphtheritic treatment for all membranous disease of the throat, without waiting for the culture diagnosis. He believes scarlatinal diphtheria, or the membranous throat seen in scarlatina, is of the true variety, even though cocci are alone found, saying that after healing of the mucous membrane the diphtheria bacillus may still survive. Some modern observers are of the opinion that this membrane formation, wherever occurring, is due to the Löffler bacillus, and nearly all concur in the opinion that true croup is diphtheria of the larynx. Henoch does not believe true croup to be diphtheria, unless the latter disease prevails endemically.

Carl Guttman believes that in cases wherein the diphtheria bacillus is not found at the time of the examination, it still existed at an earlier period, and was dominated and destroyed by later common mouth-organisms. He quotes three cases of laryngeal croup without pharyngeal diphtheria, in which the true diphtheria bacillus was found.[1] Ritter reports 29 cases of diphtheria, finding the bacillus in all and their cultivation. The detached membrane was first dipped and gently rubbed off in a weak thymol solution, then the upper layer scraped away, and small sections of the next or middle layer used to inoculate the culture media. Eberth, in 52 cases, found the bacillus in 37, negative in 15. He believes that with greater care the bacillus could have been found in all the cases. In 31 cases of angina follicularis and severe throat inflammation, he found no diphtheria organisms, only the mouth-organisms and cocci, in one case the pseudo-bacillus of diphtheria. Eberth remarks that it is always a most disturbing element to find the streptococci or the chain cocci in these examinations, because in such there is imminent danger of septic infection and inflammatory lesions in joints, pleuræ, and heart valves. Virchow draws the parallel between diphtheria and tuberculosis, both diseases existing in the form of their specific micro-organisms and as in the inflammatory processes; and that it is of importance to distinguish between the clinical and anatomical pictures.

It is recognized that medication must be directed to the removal of the fibrin-imbedded epithelium of the mucous membrane, or false membrane, and to cleanse the parts involved as well as all the contiguous passages; and then to directly apply the agents selected to remove and destroy the pathogenetic organisms—by sprays, swabbings, powderings, submucous injections, and similar manipulations by competent hands. For the first purpose, weak chlorine-water, lime-water, and weak solutions of boric acid, corrosive sublimate, creolin, and carbolic acid seem to be most used; and for the second, stronger solutions of the same, the liq. ferri sesqui-chlor. and powders composed of sulphur and quinine, bismuth, freshly powdered cubebs, and some few others not so well known.

Dr. Jaques,[2] of Marseilles, reports the methods used by him during the past three years with satisfactory results. He isolates his patients in smooth-walled and scantily furnished rooms, and institutes an accurate and precise plan of management and treatment from the very first. For instance, a child of seven or eight years of age. The first gargle is composed of one part liq. ferri sesquichlor. and two parts of glycerine; a tablespoonful of this in one-fourth part of a glass of boiled water. The second application is composed of carbolic acid in crystals, 2 grammes; glycerine, 50 grammes; distilled water, 150 grammes. These are used on alternate hours, each being preceded by a thorough douching or spraying by means of a three per cent. boric acid solution. No internal medication. For drink, diluted cognac or rum, and milk diet. The same method of treatment has practically, for some time, been in use in the Children's Hospital in Berne, with a reduction in mortality of from twenty to thirty five per cent. over former methods.

In the Children's Hospital of Munich, Professor Seitz is in the habit of using, by means of extemporized hoods over the head of the patient, large volumes of steam and vapor from a solution of eucalyptol, in the proportion of from two to five per cent. Previously—in some cases—the membranes are digested by using pancreatinine or papayotine and brought away, the latter acting with remarkable rapidity. These substances are applied in the form of pastes with camel's hair pencils. He used stimulants, fluid nourishment, and beyond mild febrifuges no internal medication. Lysol, creolin, and salol are much used in the Munich hospitals in throat affections with membrane, and in various solutions and methods—sprays, gargles, etc.

Strubling,[1] after cleansing and gargling with weak solutions of carbolic acid, sublimate (1 to 2,000), lime-water, etc., makes direct applications with iodine and phenyl solutions, and weak solutions of the liquor ferri sesquichloride. Internally he uses hydrarg. cyanur. The treatment originated by Professor Burchardt, of Vienna, is by means of frequent garglings and cleansings of the involved parts, followed by the use of a powder composed of equal parts of the flowers of sulphur and quinine, applied by a specially designed pulverizateur. No food or drink follows these applications under one and one-half hours. This method is reported as conducing to rapid exfoliation of membrane and necrotic parts, and limits the spread of the local disease. Siebelt, of Leipzig, gives 46 cases, of which number 10 were fatal; 44 were children of from six months to thirteen years of age, and 2 were adults. He uses creolin in the form of spray, in from one-half per cent. to four per cent. solutions. Leaving out 4 cases which came late under treatment—dying within twenty-four hours—the mortality was fourteen per cent. Of the total cases eighty-six per cent. were free of complications. He thinks creolin is better borne than corrosive sublimate and carbolic acid, and that it is a better remedy for use in diphtheria.

On the Continent there is not much to be found in reference to, or in favor of, the use of the peroxide of hydrogen in diphtheria, but that it has value in the common throat ulceration is hardly doubted. It is not the present purpose to enumerate all the methods of treatment in use, but only such as are based upon given results of prominent value reported recently. In a somewhat limited experience the writer has found it satisfactory, after cleansing the locally involved parts with weak antiseptic solutions, to use directly on them a one-quarter to one per cent. solution of the mercuric chloride hourly, and this whether the appearance at first is indicative of typical diphtheria, or of irregular ulceration with flakes and smears. The application must be done well and thoroughly, and a pinch of cotton wool in forceps makes a good swabbing appliance, and is at once destroyed. This method, in the great majority of instances, with or without painful glandular involvement, will clean up these doubtful throats remarkably soon. A persisting reforming membrane will be gradually overcome, and in such

[1] Roux and Yersin, d'Espine and Marignac, and Tangl.

[1] Deutsche Med. Woch., September, 1891.

cases lime-water, and steam from a lysol or creolin solution (two to four per cent.), is an additional weapon of importance. The ice-pack to the throat is also soothing and beneficial. If, in the first hours of suspected or even undoubted diphtheria, its local seat is vigorously attacked, internal medication will not be of much moment, beyond some stimulation. The best of cognac much diluted in pure water iced, and full doses of the sesqui-chloride of iron in distilled water, at two-hour intervals, are obviously of great use; and the latter is a remedy more universally used and believed in than any other. The digestive plans of getting rid of the membrane are much depended upon by some, yet they do not meet with general acceptance, because of the amount of local pain sometimes produced, and the manipulation demanded, the results in the end being questionable.

The ice treatment[1] consists in applying ice externally and internally, sufficiently long to abort all bacterial growth by reason of the reduced temperature produced. The ice-pack is applied externally to the neck, pieces of ice are left to dissolve constantly in the mouth, and the tongue, throat, and contiguous parts are sprayed with ice-water. This is easily done, even in the case of very young children. It should be followed for from twenty-four to thirty six hours without intermission, after which a pause may ensue of an hour or two. It "relieves pain and swelling of the glands, reduces fever, procures comfort, and limits the growth of the bacillus," so conducing to rapid cure. Internally this observer also used chloride of potash, the tincture of the sesqui-chloride of iron, sod. salicylate; and for diarrhœa, opiates. He reports an improved mortality, and the patients as being always grateful and treatment well borne.

The result of the immunizing of animals for periods of time, accomplished in the experiments of Behring, Kitasato, and Fränkel, by means of sterilized cultures of the bacillus, the toxic principle being gotten rid of by heating above 55° C.; and the trichloride of iodine (1 to 500), added to pure cultures, used after inoculation with the toxic products; or by the use of cell-free fluids or blood-serum of inoculated animals, are as yet too inconstant to be of any practical use. Löffler's[2] experiments with cultures of the organism with various inhibiting and destructive agents, yielded results that have been for some time in practical use. Kali chloricum was not inhibitory in five per cent. solution. Prompt destructive effects followed with the use of sublimate, mercuric cyanat., chloroform-water, and carbolic acid. In the Griefswald clinic patients are sprayed, pencilled, etc., with sublimate in 1 to 1,000; carbolic acid, three per cent. in alcohol thirty per cent.; turpentine with carbolic acid, two per cent., in equal parts every one or two hours. Prophylaxis for the well includes the use of the same agents, in weaker solution, and by inhalation as well.

There do occur severe, rare cases in private practice, the spreading, waxy, membranous throats, with fever, depression to hebetude, diarrhœa, and greatly swollen and painful glands with difficult breathing, in which one may well ask what shall be done! What steps of notification to the health authorities, proper isolation and treatment, become practicable among the crowded poor, or even with the better circumstanced middle classes? Prompt action is demanded by public sentiment, reasonable or unreasonable, and by the exigencies of the patient's condition. With it all medical minds very often may and do differ, and health boards are, unhappily more or less with us, still in politics, while the means for securing correct and rapid bacteriological or culture diagnosis are not yet common in this country. Such questions constantly and unexpectedly come up, and must be met by resolute and decided action based upon modern methods mainly. From the very first, isolation in clean, unencumbered, and well ventilated rooms must be procured, and the obvious disinfectant precautions put in force.

[1] Dr. Mayer: Therap. Monatschr., November, 1890.
[2] Deutsche Med. Woch., No. 10, 1891.

The treatment may vary according to preference based on individual experience, but regard must be had to the cardinal points of: Early correct diagnosis by a competent pathologist; cleansing by weak solutions, followed by more direct and concentrated agents in the hands of skilled nurses or the medical adviser himself, with the view of limiting the growth of the organism; and the patient must be stimulated. In the very young sprays can be introduced through the nostrils to the back of the throat, hoods can be improvised, and steam vapors of well-known agents used constantly; and the strength kept up by weak brandy, milk and lime-water. The ice-pack relieves painful glands, and lumps of ice in the mouth are grateful. The sesqui-chlor. of iron can be used as spray, and by this means much absorbed, if a preference is given to this valuable remedy. The use of membrane-digesting agents requires more care; and papayotine must be carefully handled, as it magically dissolves and destroys membrane, and may attack tissues not contemplated. In the newer substances of proved anti-bacterial value, such as creolin, lysol, aristol, and several others, not to the neglect of the sublimate and carbolic acid, there is abundant choice for remedies.

When it is apparently impossible to apply with any thoroughness this plan of management and treatment, as, for instance, among the crowded homes of the poor, their best interests, and that of the public as well, demand removal to an infectious pavilion suitably provided for such cases, and which should exist as annexes to all competent hospitals wherever located. The wealthy can provide equally safe and efficient means in their homes.

That the measures now current among the properly informed members of the profession, imperfectly touched upon in this paper, and which are based upon the now recognized etiology and pathology of the diphtheritic process, do favor rapid cure, and that they have robbed the disease in recent years of half its terrors, seems now to be substantiated by the records of large numbers of cases treated, and is felt to be the fact by many practitioners of the present day. With the knowledge to be gained by the culture examination, the treatment and prognosis become clearer. The streptococci when found contain an element of danger from septic invasion of internal organs, but with limited power of transmission; while the true diphtheria bacillus and infective agent is lethal in its direct effects, far-reaching in its consequences, and fraught with danger to life and an easy transmissibility from the sick to the well.

In conclusion, the evolution of the micro-organism of diphtheria itself is a much more difficult question. Whether, under conditions of the well-known insanitary human environment almost invariably associated with the first cases of diphtheria met with in a house or section of a city, an ordinary saprophyte enters upon another phase of growth and tissue chemistry, whereby its products become to us such characteristic lethal elements, with formation of ferments—commonly seen in vegetable organisms, and existing normally in some plants higher in the scale, especially in their seeds—the Löffler bacillus as such is evolved with all its virulent capabilities, is extremely probable, but is not proved. Or whether this organism exists always with the same potentialities, needing only the depraved conditions of health to be found in insanitary habitations, and chiefly dependent upon foul ground-water—from surface soakage, in contra-distinction to the high level of subsoil water common to some sections of flat lands—to produce the disease, is an equally plausible theory. In many minds the first proposition seems most probable, and many otherwise unaccountable circumstances in connection with the origin of cases of the disease *de novo*, would seem to be in accord with it. This chain of reasoning would equally apply with some other diseases due to microphytic causes, as the origin of typhus, typhoid, cholera asiatica, and the class as yet denominated filth diseases. It is accepted that the diphtheria bacillus exists commonly under conditions of moist

foulness, under ordinary temperatures, in sewer-pipes, drains, and damp, unconcreted cellars, in and about human habitations. That unusual physical conditions, such as great variations in barometric pressures of the atmosphere over such foul and moist soils, cause excessive "ground respiration," with an exceptional freeing of this among other micro-organisms of the saprophytic class, thus polluting the air to an unusual degree, is also quite evident. These problems are not so far advanced in their satisfactory solution as is the recent work on the points of the disease more fully dwelt upon above.

THE PREVALENCE OF CORNEAL ASTIGMATISM IN EYES WITH NORMAL ACUITY OF VISION, AND WITHOUT ASTHENOPIA.

By D. B. ST. JOHN ROOSA, M.D., LL.D.,

PROFESSOR OF DISEASES OF THE EYE AND EAR IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL.

AFTER the invention of the ophthalmometer, by Helmholtz, Donders was the first to use it for the determination of the prevalence of corneal astigmatism in ametropic and emmetropic subjects. The results of these investigations were most important. They overthrew the prevailing opinions that myopia was due in large measure to increased curvature, and presbyopia to lessened curvature of the cornea. There were also other conclusions indicated, which have been since fully settled, and on lines laid down by Donders. These will be discussed in a later part of this paper.[1] The ophthalmometer of Helmholtz involved so much time and trouble in determining the radius of curvature of the cornea, that it was little employed, except at Utrecht by Donders and his students. After the invention, by Javal and Schiotz, of a modification of that of Helmholtz, which in practical use is a marvel of simplicity, measurements of the cornea were numerously made by Javal,[2] Nordensen,[3] Schiotz,[4] Burnett,[4] and others. These examinations were upon school children and persons coming to an oculist for advice. So far as I know, there have been no results published of the examinations of a selected class, such as is enumerated in the title to this paper. Yet this examination of what passes for the normal type, and which, on superficial examination at least, shows no departure in acuity of vision, and in general functions from a normal condition, is of importance. Without such examinations we have no sufficient data upon which to form conclusions as to the full significance of the anatomical conditions. It is only by them that we can separate the ideal from the real, the normal from that which is abnormal. I have already published investigations of this kind to determine what is the prevalence of emmetropia [5] and what of equilibrium of the external ocular muscles [6] in presumably normal eyes, that is, eyes with normal acuity of vision and without asthenopia.

Believing that it is important to determine the degree of astigmatism in the cornea which does necessarily involve asthenopia, I offer a contribution to this subject, in the following table. It was prepared for me by Dr. A. Britton Deynard, an assistant surgeon of the Manhattan Eye and Ear Hospital, and an instructor in the Post-Graduate Medical School. It has required more than twelve months to secure a hundred subjects who should fulfil the indications for an examination. The subjects were obtained chiefly from the patients in the aural clinics and from the physicians attending the practice of the hospital, and from the attending and home staff. It is hardly necessary to state that every pains has been taken to make the examinations accurate. They have often been repeated and subjected to an examination from another observer than Dr. Deynard when he felt any doubt as to the fitness of the subject in the fulfilment of the conditions for examination, or as to the readings of the ophthalmometer. Nearly every one of the subjects had $\frac{20}{20}$ vision. Many had $\frac{20}{15}$. The examinations were made in a room uniformly lighted. I shall not enter into the question as to whether $\frac{20}{20}$ constitutes an absolutely perfect or ideal standard of vision, except to say that I have no idea that it does. Snellen, the author of the system, never claimed this. It is, however, a standard sufficiently exact for ordinary reference and work. From my point of view, when $\frac{20}{15}$ or $\frac{20}{10}$, or even $\frac{20}{20}-$, is easily and fluently obtained it is sufficient vision to be pronounced normal. I do not make investigations of asthenopia from the standpoint of the patient having ideal vision, or that which the most far-seeing eye can secure, but rather on the ability to use the eyes without fatigue for a proper period of time, this being coincident with $\frac{20}{20}$, or at least $\frac{20}{20}-$.

The general table is first presented. Afterward it is classified in sub-tables, and an analysis made of its results.

A Table Showing the Corneal Astigmatism of 100 *Persons, with Normal Vision* $\frac{20}{20}$ *or* $\frac{20}{20}-$, *and without Asthenopia*

Number.	Age.	Sex.	Occupation.	Vision.	Refraction by Ophthalmoscope.	Javal.

As these examinations were intended chiefly to estimate the corneal astigmatism, the examination of the axial refraction, so-called, was made by the ophthalmoscope, and

in some instances by the use of convex glasses. If atropia had been used, or complete paralysis of accommodation had been secured by any means, undoubtedly even a large percentage of hypermetropia would have been found. With the examinations as made there were nine who had no hypermetropia. The corneal astigmatism was as follows:

Table of those Who were not Found to be Hypermetropic.

No.	Age.	Sex.	Occupation.	Astigmatism.	
1	40	Female.	Dressmaker.	0.50	90
2	33	Female.	Stenographer.	0.75	90
3	23	Male.	Fireman.	1.00	90
4	38	Male.	Physician.	.25	90
5	28	Male.	Physician.	R. E. 0.50	90
				L. E.	None.
6	40	Male.	Physician.	R. E. 0.50	90
				L. E. 0.25	90°
7	21	Male.	Physician.	R. E.	None.
				L. E. 0.50	90°
8	40	Male.	Physician.	R. E. 0.25	90°
				L. E. 0.50	90°
9	25	Female.	Singer.	0.50	90°

It will be seen that not one of these who had no hypermetropia by the ophthalmoscope were without corneal astigmatism at least in one eye, but only two had sufficient corneal astigmatism (Cases II. and III. of the subtable) to require correction. One had 1 diopter, the other $\frac{3}{4}$ of a diopter. There are, then, good reasons why those comprising this table should not be asthenopic. Without hypermetropia, except of a low grade at the very most, and in only one case with astigmatism of a degree to usually warrant correction, it would be a surprise if these subjects had asthenopia from local causes.

Of the 100 five had no astigmatism in either eye. All of these were hyperopic, four to the degree of one diopter and one to that of three diopters.

With no Astigmatism.

No.	Age.	Sex.	Occupation.	Vision.	Hyperopia.
1	30	Male.	Physician.	$\frac{20}{20}$	1 D.
2	19	Female.	Student.	$\frac{20}{20}$	1 D.
3	40	Male.	Clerk.	$\frac{20}{20}$	R. 1 D.
					L. 2 D.
4	25	Female.	Housewife.	$\frac{20}{20}$	1 D.
5	24	Male.	Student.	$\frac{20}{15}$	3 D.

As far as this table indicates anything, it shows that hypermetropia of itself is not necessarily a cause of asthenopia. The one case of a moderately high degree, three diopters, was that of a student of nineteen years of age. She may yet have asthenopia if three diopters of hyperopia be sufficient to cause it. It should be remembered that all these subjects were questioned not only as to having asthenopia at the time of examination, but also as to whether they ever had had an attack of inability to continue to use their eyes in near work.

There were seven who had astigmatism in one eye only.

Astigmatism in One Eye Only.

No.	Age.	Sex.	Occupation.	Vision.	D.	Astigmatism.	
1	34	M.	Physician.	$\frac{20}{20}$	1 D.	L. E. 0.25	90

5	18	F.	Seamstress.	$\frac{20}{20}$ —	1 D.	L. E. 0.50	90
6	36	M.	Clergyman.	$\frac{20}{20}$	1 D.	R. E. 0.25	180°
7	21	M.	Physician.	$\frac{20}{20}$	None.	L. E. 0.50	90
8	40	M.	Bookkeeper.	$\frac{20}{20}$	1 D.	R. 1.00	110°

No. 2 in this case has the optical conditions to cause asthenopia. There is a considerable degree of hyperopia (3 D.) and astigmatism in one eye, of one diopter axis 45°. This subject, however, has an occupation not necessarily involving much use of the eyes upon near objects, and he may escape until he is presbyopic, when if he reads much he may require a correction of his astigmatism in one eye to be comfortable; but if he reads very little he may not need anything but spherical glasses.

Another of this table, No. 8, a bookkeeper, would be presumed to require correction of his refractive defect, for he has one diopter of hypermetropia added to a diopter of astigmatism, the latter in the right eye, axis 110°. The remainder, however, I do not think would be expected, even under considerable use of the eyes, to have asthenopia.

Thirteen had less than half a diopter in both eyes, as follows:

Less than Half a Diopter of Astigmatism in Both Eyes.

No.	Age.	Sex.	Occupation.	Vision.	D.	Astigmatism.	
1	25	Male.	Clerk.	$\frac{20}{20}$	1 D.	0.25	90
2	11	Male.	Scholar.	$\frac{20}{20}$	2 D.	0.25	90°
3	34	Male.	Weaver.	$\frac{20}{20}$	2 D.	0.25	90°
4	40	Female.	Housewife.	$\frac{20}{20}$	1 D.	0.25	90°
5	28	Male.	Physician.	$\frac{20}{20}$	1 D.	0.25	90°
6	30	Male.	Physician.	$\frac{20}{20}$	1 D.	0.25	90°
7	28	Female.	Housewife.	$\frac{20}{20}$	2 D.	0.25	90°
8	40	Male.	Physician.	$\frac{20}{20}$	None.	0.25	90°
9	23	Male.	Porter.	$\frac{20}{20}$	1 D.	0.25	90°
10	37	Male.	Physician.	$\frac{20}{20}$	1 D.	0.25	90°
11	20	Male.	Clerk.	$\frac{20}{20}$	1 D.	0.25	90°
12	25	Male.	Physician.	$\frac{20}{20}$	2 D.	0.25	90°
13	31	Male.	Physician.	$\frac{20}{18}$	1 D.	0.25	90°

Not one of this table can be said to be liable to asthenopia from refractive error, unless two diopters of hyperopia, which four of the subjects had, are thought to constitute such a liability.

Twenty-three had astigmatism of just one-half a diopter in both eyes.

Astigmatism of One-half a Diopter in Each Eye.

No.	Age.	Sex.	Occupation.	Vision.	Hypermetropia.
1	25	Female.	Singer.	$\frac{20}{20}$	None.
2	32	Male.	Physician.	$\frac{20}{20}$	1 D.
3	21	Female.	Telegrapher.	$\frac{20}{20}$	R. 2 D.
					L. 1 D.
4	39	Female.	Dressmaker.	$\frac{20}{20}$	1 D.
5	20	Male.	Bartender.	$\frac{20}{20}$	2 D.
6	27	Male.	Clerk.	$\frac{20}{20}$	2 D.
7	25	Male.	Clerk.	$\frac{20}{20}$	2 D.
8	24	Female.	Nurse.	$\frac{20}{20}$	2 D.

10	25	Male.	Physician.	$\frac{20}{20}$	1 D.
11	25	Male.	Physician.	$\frac{20}{20}$	1 D.
12	40	Female.	Housewife.	$\frac{20}{20}$	2 D.
13	19	Male.	Student.	$\frac{20}{20}$	1 D.
14	29	Male.	Mason.	$\frac{20}{20}$	2 D.
15	30	Male.	Physician.	$\frac{20}{20}$	
				R. $\frac{20}{20}$ w. 25 180	180°
				L. $\frac{20}{20}$	1 D. 180°
16	20	Female.	Clerk.	$\frac{20}{20}$	2 D.
17	39	Male.	Teamster.	$\frac{20}{20}$	2 D.
18	26	Male.	Janitor.	$\frac{20}{20}$	2 D.
19	13	Male.	Student.	$\frac{20}{20}$ —	1 D.
20	40	Female.	Dressmaker.	$\frac{20}{20}$	None.

In only one of these, No. 15, a physician, was the axis 180° (astigmatism against the rule). Here we might expect asthenopia, or at least if it occurs, we certainly would explain it by the existence of half a diopter of astigmatism against the rule. In none of the other of this table of twenty cases should we expect asthenopia. The astigmatism equalled 0.75 of a diopter, as follows, in two subjects:

No.	Age.	Sex.	Occupation.	Vision.	Hyperme-tropia.	Axis of As.
1	23	Female.	Seamstress.	20/20	2 D.	90°
2	33	Female.	Stenographer.	20/20	None.	90°

Three-fourths of a diopter (axis 90°) is the first degree of corneal astigmatism that I am in the habit of correcting. One of these patients it will be noted had two diopters of hypermetropia.

Twenty-five, or one-fourth of the whole number, had 1 D. of astigmatism in each eye, as follows:

No.	Age.	Sex.	Occupation.	Vision.	Hypermetropia.
1	12	F.	Student.	20/20—	1 D.
2	26	M.	Waiter.	20/20—	1 D.
3	25	F.	Dressmaker.	20/20—	1 D.
4	18	F.	Dressmaker.	20/20	1 D.
5	22	M.	Clerk.	20/20	1 D.
6	32	M.	Sailor.	20/20	1 D.
7	26	M.	Gardener.	20/20	1 D.
8	26	F.	Housewife.	20/20—	1 D.
9	23	M.	Fireman.	20/20	None.
10	32	F.	Housewife.	20/20	1 D.
11	28	F.	Housewife.	20/20	1 D.
12	19	F.	Housewife.	20/20	2 D.
13	23	F.	Housewife.	20/20	2 D., R. E. 85°
14	23	F.	Housewife.	20/20	2 D.
15	16	F.	Student.	20/20	1 D.
16	22	F.	Dressmaker.	20/20	R. E. 2 D. L. E. 1 D.
17	18	M.	Clerk.	20/20	2 D.
18	15	F.	Clerk.	20/20	1 D.
19	21	F.	Housewife.	20/20	1 D.
20	25	F.	Dressmaker.	20/20	1 D.
21	24	F.	Music-teacher.	20/20	1 D., R. E. 75° L. E. 90°
22	11	M.	Student.	20/20	2 D.
23	18	F.	Dressmaker.	20/20	1 D.
24	35	M.	Clerk.	20/20	1 D.
25	21	F.	Teacher.	20/20	2 D.

In this table the symmetry of the conditions is interesting. The axis was 90° in all of the cases but two. In one eye of one of these, it was 85°. In one of the others it was 75°. The hypermetropia also was one diopter in two-thirds of the subjects. In one case there was none. In seven cases it was two diopters.

In four of the subjects the corneal astigmatism was more than one diopter in both eyes, as follows:

No.	Age.	Sex.	Occupation.	Vision.	H.	Axis.
1	30	Male.	Clerk.	20/20	3 D.	1.25
2	28	Female.	Housewife.	20/20	1 D.	1.25
3	14	Female.	Student.	20/20	3 D.	3.00 105° 90°
4	22	Male.	Driver.	20/20	1 D.	1.25

No doubt the third one of the table, who was one of fourteen other students examined, if she remains a student or in any occupation requiring close use of her eyes, will require glasses, for she has three diopters of astigmatism, added to three diopters of hyperopia. The others may easily escape the need of correction of the astigmatism until presbyopia comes upon them.

In twenty-six of the subjects the eyes of the same subject differed in the degree of astigmatism as follows:

No.	Age.	Sex.	Occupation.	Vision.	H.	Axis.
1	34	M.	Physician.	20/20	1 D.	R. None. L. 0.25
2	32	M.	Bricklayer.	20/20	1 D.	R. 1 D. L. 1.50

26	19	F.	Dressmaker.	20/20	2 D.	R. 0.50 L. 0.25

The analysis of this table shows that eight were under twenty years of age, so that their danger from asthenopia is by no means past. The axis of astigmatism was 90° except in four cases. In one it was against the rule on both sides, or axis 180°.

It is seen at a glance that 13 of the 100, namely, the two waiters, the bricklayer, the two porters, the gardener, the janitor, the fireman, the mason, the bartender, the car-driver, the sailor and teamster, had occupations that did not necessarily or probably involve any use of the eyes on fine or near objects. Undoubtedly such subjects have immunity from asthenopia, as compared with persons like the others of the total number, who must of necessity use their accommodative power very considerably, and in the case of seamstresses and dressmakers generally beyond proper limits; but it never should be forgotten that sound eyes, like other sound organs, are the better for use.

I should have much preferred to make these examinations only upon persons of the age of at least twenty-five years. The school-children in the list are not so good observers as to the existence of asthenopia, nor can they be said to be beyond the danger of it, until they have come to years when study, seriously and for several continuous hours, is habitual. But it is very difficult to secure even the class I have found with closer discrimination than Dr. Deynard has made. We have therefore made this presentation as a fair beginning only of a line of investigation which promises considerable addition to our knowledge of the normal refraction of the eye. I shall not attempt to make many deductions from the facts of the table until they have been confirmed by subsequent observations with the ophthalmoscope and ophthalmometer by myself or others. This much I can say, however, the table adds to the already overwhelming evi-

dence that emmetropia is an ideal condition. It is doubtful if the use of atropia would have left one case of the general table that was neither hypermetropic in the axis of the eye or in the cornea. Negatively, the fact that the larger proportion of these had not the condition, that is to say, a considerable degree of astigmatism, that would lead us to expect asthenopia, were it uncorrected, while nearly all had hypermetropia, and of a decided degree, leads us to believe that hypermetropia is not a powerful factor in producing asthenopia, and that Donders's teaching remains true, that one to two diopters are readily overcome in youth. This I believe to be the accepted doctrine, except among those who believe that all hypermetropic eyes should be corrected into emmetropic by glasses.

I consider in analyzing the table of 100 that eleven had optical conditions that would generally be considered sufficient to account for asthenopia did it occur.

Occupations.

Physicans	18	Teacher	1
Students	13	Singer	1
Dressmakers or Seamstresses	12	Weaver	1
Clerks	12	Bookkeeper	1
Stenographer	1	Clergyman	1
Silk-picker	1		
Telegrapher	1	Total	64
Music-teacher	1		

The above table may be said to comprise those who have asthenopic occupations.

Non-asthenopic Occupations.

Nurses	2	Fireman	1
Waiters	2	Mason	1
Bricklayer	1	Bartender	1
Porters	2	Car-driver	1
Teamsters	2	Servant	1
Sailor	1		
Gardener	1	Total	36
Janitor	1		

A careful and frequent reference to Donders's writings upon refraction and accommodation shows that he omitted very few of the principles upon which an exact knowledge of this subject depends. What advances have been made are upon lines that he clearly laid out, even if he did not always see all that is actually on them. On the subject of the axis of greatest curvature of the cornea he was very positive, although the knowledge of astigmatism as a frequent anomaly was very recent and first demonstrated by him. Some of the observations of his time do not fully agree with him in all points, but he usually turns out to be right. For example, he says:[1] "As to the normal (astigmatism), the cause is in general, for the most part, to be sought in the cornea and the direction of the principal meridians, for the whole dioptric system, as well as for the cornea in particular, is of that nature that the meridian of maximum of curvature usually approaches to the vertical, that of minimum to the horizontal."

Again[2] he says: "Absolute emmetropia in one of the principal meridians is a condition not easily met with."

Donders is sometimes erroneously quoted as saying that $\frac{1}{40}$—about a diopter—of astigmatism may be considered normal, but he says exactly the reverse of this, for example: "If it (corneal astigmatism) amount to $\frac{1}{40}$ or more, it must be considered as abnormal." Then again he is more emphatic (on page 512): "Boundaries between normal and abnormal astigmatism do not exist when it attains the degree of $\frac{1}{40}$ (1 diopter). I have called it abnormal because the disturbance of vision is of that nature that cylindrical glasses are desirable for its improvement, but otherwise it is evident that the limit I have fixed upon is rather arbitrary. With much slighter degrees the acuteness of vision is no longer perfect."

Donders then goes on to show that an astigmatism in his own eyes of about $\frac{1}{100}$ was capable of being improved by cylindrical glasses. He criticises Knapp's standard of normal astigmatism as being too high. He also says that of forty to fifty eyes one at least is disturbed in its functions by astigmatism. With his exact knowledge of the frequency, the axis of greatest curvature, the degree of what constitutes an abnormal astigmatism, Donders marked out the road on which many of us are now travelling; that is to say, that astigmatism, and not hyperopia, is the dominant cause of asthenopia. Important as is the axial length of the eyeball in one respect, the acuity of vision, in the production of asthenopia, the corneal astigmatism is more important. I do not claim that this is Donders's teaching. He did not know of the frequency of astigmatism of a considerable degree. He could not then teach this. It was his idea that hypermetropia was at the bottom of most asthenopia; but I do claim that this doctrine, with our increased facilty in determining the degree of astigmatism, is legitimately deduced from the principles that he laid down in discussing astigmatism.[1]

Donders is very clear on the subject of the lessening of the corneal astigmatism by the lens. He thinks that occasionally the lens may increase the corneal astigmatism, but commonly[2] it diminishes it. He says that the lens may take part in astigmatism in two ways, "by the form of curvature, and by an oblique position." Those who lightly estimate the ophthalmometer as a means of determining the degree and axis of astigmatism are constantly speaking of this action of the lens, as if it were something that cannot be estimated, and which destroys the value of the readings of the Javal and Schlotz instrument. The measurement of thousands of eyes by the ophthalmometer in the hands of Javal and his followers, has demonstrated the truth of Donders's statement that the lens commonly lessens corneal astigmatism—and this is a recent observation—by about one-half, a diopter when the axis is 90°, while none at all when the axis is 180° in hypermetropic eyes, and 90° in myopic. Donders attached great importance to Helmholtz's instrument. If that from which calculations must be made after the corneæ were measured was so highly esteemed, how much more valuable the modern instrument, which notes the astigmatism and makes the calculation for us, and that in a moment of time.

Keeping Cholera out of Cuba.—The Cuban health officials have a wholesome dread of cholera, as great perhaps as that of the dwellers about the Great South Bay, and they were determined that the disease should not get at them by way of New York. In September last a steamer left New York with a clean bill of health for Cuba. When she arrived, a week later, at Guantanamo the health officer of the port rowed within hailing distance and shouted out to have the passengers and crew mustered up on deck. He counted them and had them sent below, and then came near enough to the ship to get the bill of health. This he sprayed carefully with carbolic acid and then read it to see if it tallied with his count. Then he went away leaving the vessel in quarantine. At the end of four days he ventured aboard, fumigated the boat and sprayed each passenger and member of the crew with carbolic acid. After this he boldly released the ship. From this port the ship went to Santiago. There she was fumigated and the passengers and crew were made to march around a pot of burning sulphur on deck. After leaving Santiago the vessel proceeded to Cienfuegos and there was fumigated and sprayed again. Then she came back to New York, and Cuba was left with her yellow fever all alone.

[1] In a paper upon the asthenopia of astigmatic individuals, Dr. George T. Bull, of Paris, formerly of New York, read before the French Ophthalmological Society, states his belief that asthenopia is most frequent in astigmatism direct (according to the rule), and in mixed astigmatism. He classified astigmatism as direct, inverse, oblique, and mixed (*Comptes Rendus de la Société Française, d'Ophthalmologie*).

FEEDING IN FEVERS.[1]

By GEORGE L. PEABODY, M.D.,

NEW YORK.

In opening the discussion this evening, I wish to say that I am here to learn rather than to teach, and to find out from my colleagues who are present whether they do not think that it is common in practice to-day to adhere too rigidly to older methods in feeding fever patients. I refer not only to the continued fevers, but to the eruptive fevers and those that occur with many varieties of inflammations. In following other physicians in the hospitals to which I am attached, *i.e.*, in succeeding them in attendance each year when my term of duty begins, I always find a certain number of fever patients, and I usually find that they are allowed only fluid foods. Of these foods milk is the most important. Milk seems to be generally regarded as a fluid, and a very harmless-looking fluid it certainly is when it is put into the stomach; but if it is to be digested and assimilated at all, it is very soon transformed into a bulky solid after it reaches the stomach.

There are many patients to whom milk in any form is repugnant, and to some of these it is exceedingly difficult of digestion. It has been my practice for many years, in all kinds of illness, but especially in the presence of fever, to pay regard to the appetite and desire of the patient. If a patient is really hungry solid food of a properly selected kind and in judicious quantity will rarely disagree with him. With hospital patients it is not always easy to ascertain whether they are really hungry. Many will profess hunger without being hungry because they suppose that they will recover more quickly if they eat freely. To them, of course, other solid food than milk should not be given, but if they are genuinely hungry I believe it is safe to presume that the stomach is prepared again to resume its function, that gastric juice is again secreted, and that properly selected albuminous food in judicious quantity will be digested if you give it.

We are accustomed, I think, to have too great a dread of doing harm at the site of lesion in the ileum in typhoid fever by giving solid food. If I am correct in my opinion as to the inference to be drawn from hunger in a fever patient, there is even less likelihood of causing damage to an ulcerated ileum by giving finely divided egg or beef or chop to such a patient than by giving him milk; and my experience seems to justify the inference. It has been my practice for years to allow albuminous foods of these descriptions to such patients, even before the fever leaves them, under these conditions. I have at present under treatment several patients with typhoid fever whose temperatures reach 101°, 102°, and 103° F., daily, who are hungry, and who are receiving such solid food once a day. So far as I am aware I do not have a larger percentage of relapses or hemorrhages or other serious complications or accidents in my practice than I did before I adopted this plan, or than my colleagues do who have not yet adopted it.

Even tea and coffee and beer are not allowed by many doctors; in my hands they have been very useful when given to those who have been accustomed to them in health and desire them in fevers. Well-cooked oatmeal is another very nutritious food that I allow under the same conditions as meat.

When the appetite fails, in consequence of the presence of fever, meat becomes more repugnant than any other food as a rule. Then it would be most injudicious to force it upon a patient; but the returning appetite, the awakening desire for meat, I believe to be nearly always an indication that the stomach is prepared to take care of it. That much is gained by maintaining the nutrition of fever patients needs not to be mentioned to the members of this Society. Of course, the necessity of giving an abundance of water is not to be lost sight of.

[1] Remarks at a meeting of the Practitioners' Society, November 4, 1892.

What I have said of feeding typhoid-fever patients is equally true in other forms of fever. It is, in my judgment, a mistake to withhold solid food merely because a patient has fever, and it is incorrect to regard milk as a fluid food, as our knowledge of the physiology of digestion teaches us. Our knowledge of the form in which milk often appears in the fæces emphasizes this latter fact. Milk will always remain the most serviceable general food in disease, and especially in fever, largely because it is swallowed with much less effort than attends the taking of other foods; because it is the cheapest of the foods; because it requires little or no preparation, and because it is so commonly well borne. But where it fails to nourish the patient, where it is not well borne, where it cannot be taken, for any reason, it is well to remember that efficient adjuncts and substitutes are within reach.

INTRA-UTERINE INJECTIONS OF GLYCERINE.

A Simple, Safe, and Efficient Means for the Induction of Labor, and the Stimulating of Uterine Contractions.

By J. CLIFTON EDGAR, M.D.,

ATTENDING PHYSICIAN TO THE ASYLUM OF THE NEW YORK LYING-IN HOSPITAL; ASSISTANT OBSTETRIC SURGEON TO THE NEW YORK MATERNITY HOSPITAL.

Case I. *Pelvic Contraction.*—Seen in the service of the Asylum of the New York Lying-in Hospital. Both parents of this patient are living and apparently healthy. The mother's height is four feet seven inches; she has had nine children, and states that no difficulty was experienced in her labors.

Of the four daughters the eldest died as the result of an abortion, occurring at the third month.

The second daughter, thirty years of age, is four feet eight inches in height, and has had four children at term and two abortions, at the seventh week and third month respectively. All the children born at term were still born, although, as she states, "she felt life up to the last moment" before going into labor. The first labor, at term, was difficult and prolonged, and the second and third were instrumental.

The third daughter is twenty-six years of age, has been married four years, and is four feet eight inches in height. She has had two children, of which the first was still-born at full term.

The fourth daughter is twenty-five years of age, and is four feet seven and one-half inches in height, and has given birth to one child, which was delivered by instruments at full term after a prolonged labor, and only survived a few hours.

This woman was first seen by the writer on October 27, 1892, at 10.30 A.M., and found to be about thirty-eight weeks pregnant. She was well-nourished, cheerful, and had an erect attitude; varicose enlargement of the veins of the lower extremities were present, but no œdema. Urine, alkaline, 1.020; no albumin, no sugar. Fœtal movements to the left and strong; fœtal heart-sounds strong and 148 to the minute.

The following pelvic measurements are recorded: Distance of fundus from symphysis, 13 inches; distance of ensiform from symphysis, 14 inches; distance of umbilicus from symphysis, 6 inches; circumference of abdomen at umbilicus, 34 inches; circumference of pelvis, 33 inches; distance between spines, 8½ inches; between crests, 10 inches; between trochanters, 11 inches. The conjugata vera was estimated to be 3½ inches, after three observers had measured the same independently and their results compared.

As the woman became pregnant soon after her last confinement, there was no menstrual period from which to estimate the duration of gestation.

Taking into account, however, the height of the fundus, the size of the fœtal head, the length of the fœtal ellipse, and the amount of dilatation at the internal os,

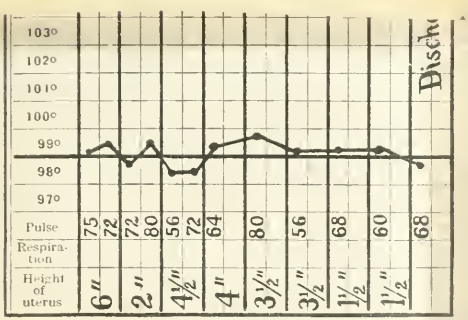
it was estimated that the patient was still within two weeks or ten days of full term.

Recalling the previous history of the woman and of her sisters, the writer decided that the interests of the child, to say nothing of the mother, demanded the induction of premature labor, which was immediately performed in the following manner :

The woman was brought to the edge of the bed, the bladder emptied, and the vulva and vagina were scrubbed with green soap and water, and, finally, with a solution of the bichloride of mercury, 1 to 2,000. Then, under the strictest aseptic and antiseptic precautions, the anterior cervical lip was seized in the grasp of a double volsella forceps, and the cervix drawn down nearly to the vulva. The internal os was found to admit the point of the index-finger. Half an ounce of sterilized glycerine was then slowly injected between the membranes and the uterine wall by means of a No. 9 (English scale) braided silk catheter, connected with a simple glass syringe. The catheter was introduced to a distance of eight inches from the external ring of the cervix. No pain was apparently caused by the operation, and the woman, in the dorsal position, with her hips raised by pillows, was left in the charge of a physician.

The injection was made at 11.30 A.M., October 27, 1892. At 2 P.M. strong uterine contractions set in, and at 8.05 P.M. the third stage of labor was completed.

The membranes ruptured spontaneously at the end of the first stage : vaginal secretion was moderate in the first [illegible] in the second ; the pre-



Record of the Puerperium.

The mother made an uninterrupted recovery. At no time during the puerperium did the temperature rise above 99.2° F. The child at the present writing is still living and in excellent health. Nothing can exceed the happiness of the mother in obtaining a living child, because from her own experience and that of her sisters' she had come almost to look upon such an event as an impossibility.

Summary of Labor.—Intra-uterine injection of one-half ounce of glycerine, October 27, 1892, 11 30 A.M.

First Stage.—Began October 27, 1892, 2 P.M.; terminated, 7.30 P.M. ; duration, 5 hours 30 minutes.

Second Stage.—Began October 27, 1892, 7.30 P.M.; terminated, 8 P.M. ; duration, 30 minutes.

Third Stage.—Began, October 27, 1892, 8 P.M. ; terminated, 8.05 P.M. ; duration, 5 minutes.

Total duration of labor, 6 hours 5 minutes.

Temperature at beginning of labor, 99.01° F. ; at end of labor, 98.2° F.

Pulse at beginning of labor, 84 ; at end of labor, 72.

Height of fundus, one hour after delivery, above symphysis, 5½ inches.

CASE II. *Low Implantation of the Placenta.*—This case was seen by the writer in the service of the New York Maternity Hospital, Blackwell's Island.

Patient was twenty-six years of age ; American ; domestic ; IV.-para. Previous to the present pregnancy has suffered from one abortion and one miscarriage ; was admitted to the Maternity, September 8, 1892, stating that her last menstruation occurred February 26, 1892, and quickening, June 1, 1892.

In June last, as the result of traumatism, symptoms of threatened abortion, pain, and hemorrhage were present for a short time. Subsequently, at intervals, there were slight hemorrhages until September 29, 1892, when a hemorrhage occurred which necessitated her being confined to her bed for several days. Slight blood losses took place at intervals until October 26, 1892, when the loss of several ounces of blood occurred, and the patient was kept quiet in bed until her confinement.

Upon October 26, 1892, the patient was seen by the writer for the first time, and upon vaginal examination the head was readily made out, together with a somewhat firm mass, which latter lay to the left of the head within the lower part of the uterus and caused the head to rest upon the right brim of the pelvic excavation.

At this examination the writer dilated the internal ring of the cervix with the index-finger, and after passing it into the uterus as far as the second joint, the edge of the placenta could be distinctly felt attached to the uterine wall, one and one-half to two inches above the internal ring upon the left side. Patient's temperature was normal ; pulse, 82 ; urine, normal ; fœtal heart-sounds somewhat feeble, and 142 ; pelvic measurements show nothing unusual.

Upon November 13th, in the night, hemorrhage to the extent of several ounces occurred, and the writer saw the patient again November 14th, at 11 A.M.

Patient's pulse at this time was 64 ; temperature, 98.5° F. ; respirations, 22 ; fœtal heart-sounds, 128 ; fœtal movements moderately vigorous, and to right side of abdomen.

Although the blood loss had been comparatively small in amount, yet the patient presented an extremely anxious countenance, an irritable pulse, which the most trivial cause affected, and a constant dread of a recurrence of the hemorrhage.

It was thereupon decided that the interests of the child as well as the mother demanded the emptying of the uterus.

Accordingly, at 12.25 A.M., November 14, 1892, I introduced into the uterus, in the presence of the Maternity staff, without much difficulty, after dilating the internal os with the index-finger, half an ounce of sterilized glycerine.

The catheter in this instance, a No. 10 (American scale) with a small bulbous point, was of braided silk, and twelve inches of its length was passed into the uterus before the glycerine was slowly injected. The same precautions were used as in Case I. Upon the catheter being slowly withdrawn, the smallest sized Barnes's dilator was placed in the cervix and injected with creoline solution, one half per cent.

At 11.55 A.M., thirty minutes from the introduction of the glycerine, good uterine contractions were present, and the first stage of labor was well under way. At 1.30 P.M.

the Barnes's bag was expelled from the cervix, and was replaced by the largest size, great care being taken to preserve the membranes intact. At 3 P.M. this latter dilator was expelled, and at 3.30 P.M., the head not engaging in the pelvic brim, one ounce more of glycerine was injected high up between the membranes and uterine wall as before. Soon afterward the head engaged, and the first stage was completed at 9 P.M., when the membranes ruptured spontaneously, and this was followed by the completion of the second stage at 9.20 P.M., the placenta almost immediately following.

During the first and second stages not more than three ounces of blood was lost, and somewhat less than usual at the termination of the second stage and during the third.

The child, a female, four pounds seven ounces in weight, was born somewhat asphyxiated, and was exceedingly feeble and poorly nourished, and its measurements corresponded to about the thirty seventh week of gestation. It was resuscitated, but lived only four hours.

Summary of Labor.—Intra-uterine injection of half ounce of glycerine, November 14th, 11.25 A.M.

Second injection of one ounce, at 3 30 P.M.

First Stage.—Began November 14th, 11.55 A.M.; terminated, 9 P.M.; duration, 9 hours 5 minutes.

Second Stage.—Began November 14th, 9 P.M.; terminated, 9 20 P.M., duration, 20 minutes.

Third Stage.—Began November 14th, 9.20 P.M.; terminated, 9.35 P.M.; duration, 15 minutes.

Total duration of labor, 9 hours 40 minutes.

Pulse before delivery, 82; after, 64.

Temperature after delivery, 98.5° F.

The mother made an uninterrupted recovery, the maximum temperature, pulse, and respiration markings recorded for the first seven days of the puerperium being 99° F., 84, and 24 respectively.

Remarks.—The report of Pelzer's five cases—four successful—of the induction of premature labor by the intra-uterine injection of glycerine caused the writer to make use of the same method in the two cases above narrated.

Although it would be perhaps unwise to draw any conclusions from so small an experience, yet the method certainly appears to possess all that Pelzer originally claimed for it.

The amount of glycerine used (one-half ounce) was smaller in my cases than in those of Pelzer, who used from an ounce and three-quarters to four ounces.

My experience with the second injection of one ounce in Case II., to strengthen the uterine contractions, would certainly induce me to use large amounts in subsequent cases, although half an ounce of the glycerine caused labor pains to appear in two and a half hours in Case I., and in thirty minutes in Case II.

Pelzer used the method to stimulate already existing uterine contractions, and found that feeble pains were strengthened by the injection.

The effect of the second injection in Case II. could be almost immediately observed, and resulted in the head of the fœtus engaging and descending into the pelvic cavity.

It was not found necessary to resort to the knee-chest or semi-prone positions, as in no instance did glycerine follow the withdrawal of the catheter. The pelvis in each case, however, was elevated by pillows.

No great difficulty was experienced in the introduction of the catheter in either instance; it was allowed to take the direction of least resistance in Case I. and that direction was along the posterior uterine wall. In Case II., however, the catheter was directed along the right uterine wall to avoid further separation of the placenta, and as the head in this case blocked the way it was easily raised and held to the left by the hands of my assistant.

The drawing down of the cervix by means of a volsella forceps the writer believes to be of importance, as he feels sure the passage of the catheter in both instances, but more particularly in Case II., would have been attended with great difficulty, if not rendered altogether impossible, had this not been done.

No hemorrhage followed the operation in either case; in the first case the catheter was not even stained with blood, in the second a few drops of blood were observed about the eye of the catheter when withdrawn.

It need not be added that the strictest aseptic and antiseptic measures should be observed.

The glycerine used was first boiled in an evaporating dish and then conveyed directly to a bottle which, together with its cork, had been boiled for a considerable time.

To avoid the introduction of even the smallest amount of air, a catheter with a solid tip was used in Case II., and in Case I. the tip was rendered solid by filling it with a mixture of plaster of Paris and iodoform.

The chemical affinity of the glycerine for water resulted in so great a serous discharge from the uterus that several times those in charge of the labors believed that the membranes had ruptured, which subsequent examination proved to be untrue.

Further investigation alone can determine whether this chemical property of the glycerine, or its action as a foreign body in the uterine cavity, or the mechanical separation of the membranes, or all three, determines the onset of labor in this new method.

115 East Thirty-Fifth Street.
November 22, 1892.

[1] Archiv für Gynakol., Band xlii., Heft 2.

Psorospermosis.—Dr. Boeck reviewed, in the recent International Dermatological Congress, the history of Darier's disease, and showed photographs of the four cases which he had himself observed. The speaker could not agree with Darier as to the nature of the round corpuscles described by him and regarded as parasites. He believes them to be simply altered cell-elements.

Dr. Neisser thought two diseases offered special facilities for the study of psorosperms: Paget's disease and molluscum contagiosum. In the first the parasitic nature of the disease is not yet established. For molluscum we may consider the matter a settled fact. He had succeeded in following nearly every stage in the evolution of these corpuscles, and determined the fact that they correspond almost entirely with the psorosperms from the liver of the rabbit.

Can School Children be Intellectually Over-tasked?—Professor Charcot, of Paris, has expressed himself as follows upon this important subject (*The Alienist and Neurologist*): I am not prepared to believe in the possibility of exacting and effecting excessive work with young pupils. In the higher technical schools I must admit the danger; but in the elementary and middle classes, up to a certain age and grade of instruction, it appears to me to be extremely improbable. I do not believe it practicable to overtax a child with study and instruction. It has too low a sense of responsibility. If you put to it a ques-

tion, of the answer to which it knows nothing, it simply does not reply. I remember perfectly well how, as a child, I behaved when something repugnant to my inclination was required of me. I simply did not do the thing demanded, but something else. At an appropriate age one may certainly be intellectually overburdened, but it is not in the age of childhood. It has been the very rarest of my experience to encounter neurasthenia in children. I do not, of course, now speak of that species of overtaxation which takes place in unhealthy and overcrowded rooms, where bad ventilation produces *ennui* and engenders disease. I mean purely intellectual overtaxing; and I do not believe that this occurs in children. Only when children reach the age of fifteen or seventeen years, and begin to undergo serious examinations in their school work, can any talk be made of overtasking. Nor must we then confound with the latter condition a disease which I have termed *cephalæa adolescentium*. Children who suffer from this disease are afflicted with unceasing headache, and study becomes absolutely impossible. Neurasthenics experience abatement and pause in their headaches, whereas in the disease which I have named there are no remissions. The sufferers usually belong to nervous or arthritic families. They complain of palpitation of the heart, and latterly hypertrophy of this organ has been established in such adolescents. But the morbid state of which I speak has no connection whatever with overburdening at school. Nor must we fancy that it can be dispelled by rest or ordinary therapeutic means. It is extremely obstinate, and successfully resists all medical treatment. I advise you to subject such patients to the rudest kind of physical labor. If they have reached the appropriate age for military duty I counsel you not to discourage them from service under the flag. On the contrary, urge their parents to force them into it. I have known boys who suffered from *cephalæa adolescentium* to such an extent as to be incapable of all reading and study, not only to render efficient service as cavalry soldiers or dragoons, but thereby to experience the most gratifying recovery. I once told a father that his son would get well of this trouble by exposure to rude physical work. I lost both father and son from sight; but a year later the former wrote me, "I have good news to give you of my son." He had sent the tender youth to a fisherman at Arcachon, to accompany and assist the latter in his rough and strenuous employment. He pursued it seven or eight months, and thereby surmounted his disease utterly and permanently. The cold-water cure has also been successfully applied to the removal of these headaches of adolescents, but the cure is of much longer duration. The surest process consists in removal from all former surroundings and habits, and in subjection to gross physical labor. Military service is, in my judgment, pre-eminently helpful. I would remark that I have seldom or never met this disease among children of the working classes.

Sore Nipples.—Dr. Oehren recommends ichthyol in the treatment of sore nipples, according to the following formula:

℞.	Ichthyol	1 drachm.
	Lanolin	1½ drachm.
	Glycerin	1½ drachm.
	Olive oil	2½ drachms.

—*Therapeutische Monatshefte.*

Etiology of Intra-uterine Fractures.—A paper upon this subject is published by Sperling. The results attained by his researches may be summarized as follows (*American Journal of the Medical Sciences*, November, 1892): Many cases of alleged intra uterine fractures, especially of the lower extremities, are malformations, and not fractures at all. These defects have, as a rule, nothing to do with a fracture should one be found in addition. Fracture and malformation are not produced by a common and contemporaneous cause; malformations undoubtedly occur in the first and second month of intra-uterine life, and are most rationally referred to amniotic adhesions. Bending and malformation of the extremities in these cases of supposed fracture find their most rational explanation in a precipitate flexion of undifferentiated layers in the embryo; the presence of an apparent scar is not an evidence of fracture. It is exceedingly doubtful if external violence can produce fracture of the fœtal thigh, as the fœtus is so well protected by the amniotic liquid. If intra-uterine force be held to be the cause of such fracture, such can only occur during contractions of the uterus; there is, however, no case clearly proven in which, during the stage of dilatation or of expulsion, uterine contractions alone have caused fracture; the great frequency of births at full term, accompanied by so called intra-uterine fracture, renders the theory that such fractures are caused by the irritation of the uterus in premature birth scarcely probable. In cases of fracture of the fœtal skull following severe injury to the mother's abdomen, rupture of the uterus is usually produced, and this explains the occurrence of the fœtal fracture. In so-called intra-uterine fracture of the thigh it is indisputable that but little callus is present, although the conditions are favorable for a very free development of callus. In fractures of the clavicle, the occurrence of considerable callus is best explained by defect in the development of the clavicle during embryonic life. The conditions of embryonic life account for the small amount of callus in malformations of the inferior extremities. Fractures of the lower extremities with free development of callus show no defect in the fibula or in the toes, such as is observed in cases of lack of development. A microscopic examination in a case of flexion of the bones of the forearm in a new-born child, with thickening of the bones at the point of deformity, but without defect in the fingers, showed the same pathological processes, and no characteristic callus of fracture. The conclusion of Sperling's research is that most of the cases where fractures of the bones of the extremities are supposed to have occurred *in utero* through violence are clearly cases of malformation and defective development.

Presence and Localization of Mercury in the System.—Dr. Ullmann (*International Dermatological Congress Report*) has made an experimental study of the distribution and storing up of mercury in the various organs of the body, and the methods by which it is eliminated. Ludwig's process for determining the presence and quantity of mercury was employed. This consists in adding to the suspected liquid finely powdered oxide of zinc. This precipitates the mercury, which can then be collected and weighed. If an organ is to be tested it is cut into small pieces, treated with a twenty per cent. hydrochloric acid solution, and heated for several hours. The vaporized mercury is collected and condensed in a refrigerating apparatus. Mercury was thus discovered whenever it had been administered, and especially when by the hypodermic method. The greatest quantity was found in the kidneys, liver, spleen, and intestinal canal. The large intestine contained the most and the stomach the least. An interesting point was that in the salivary glands only minute traces of mercury were to be discovered, and, strangely enough, the saliva contained absolutely none. This makes it appear that salivation due to mercury should only be looked upon as a reflex phenomenon. Mercury leaves the system through the bile, still this fluid was found to contain but little. Healthy bones showed scarcely a trace.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, November 26, 1892.

THE PAN-AMERICAN MEDICAL CONGRESS AND ITS PROSPECTS.

AT a meeting of the American Medical Association, May 5, 1891, the following resolutions were passed:

"*Resolved*, That the American Medical Association hereby extends a cordial invitation to the Medical Profession of the Western Hemisphere to assemble in the United States in an Inter-Continental American Medical Congress.

"That the Committee on Nominations be, and is hereby instructed, to nominate one member for each State and Territory, and one each from the Army, Navy, and Marine Hospital Service, who shall constitute a committee, which is hereby instructed to effect a permanent organization of the proposed Inter-Continental American Medical Congress, and to determine the time and place at which the same shall be held."

Pursuant to this a committee of forty-nine gentlemen was appointed. This Committee effected an organization of the Congress. The President is Dr. William Pepper, with whom there are seventy-three Vice-Presidents, each representing one of the United States, and the different Central and Southern American States, the West Indies, and Canada. The Secretary-General is Dr. Charles A. L. Reed, of Cincinnati, O. There are also nine Assistant Secretaries. The Vice-President for New York is Dr. Seneca D. Powell. The Secretaries are Drs. Ferd. C. Valentine and A. Walter Suiter. The Treasurer is Dr. A. M. Owen, of Evansville, Ind.; the Chairman of the Committee on Arrangements is Dr. Samuel S. Adams, of Washington, D. C. There are six Incorporators, and a Board of Trustees, fifteen in number, of which the New York representative is Dr. George F. Shrady. There are also an Executive Committee of seven, and an International Executive Committee of twenty-two. The Committee on Ways and Means consists of seventy-five gentlemen representing different States. The Congress is to meet in twenty-two sections, each of which has number

lish. The regulations adopted require that "contributors forward abstracts of their papers, not to exceed six hundred words each, to be in the hands of the Secretary-General not later than the tenth of July, 1893. These abstracts will be translated into English, French, Spanish, and Portuguese, and will be published in advance of the meeting for the convenience of the Congress; no paper will be placed upon the programme which has not been thus presented by abstract. Abstracts will be translated by the Literary Bureau of the Congress at the request of contributors Papers to be presented to sections must not consume more than twenty minutes each in reading, and when of greater length must be read by abstract. Papers read by abstract may be printed in full in the Transactions, subject to approval by the Editorial Committee. Papers and discussions will be printed in the language in which they may be presented. All papers read in the Sections must be surrendered to the Secretaries of the Sections, and all addresses read in the General Session must be surrendered to the Secretary-General as soon as read; and all discussions are to be at once reduced to writing by the participants."

It will be seen from the foregoing that a most elaborate scheme of organization has been effected, and one that has already called for a great expenditure of time and executive skill.

The Congress is to be held in Washington rather than Chicago. This, on the whole, will prove satisfactory; for few foreign visitors will wish to leave without seeing the nation's capital.

The scientific and practical results of the Congress will be watched with a great deal of interest. There is no doubt that they will be far-reaching and valuable. It will establish more closely a bond of unity among physicians of this hemisphere and lead to more fruitful efforts. The Southern republics contain good universities and many talented physicians; yet little scientific work has yet been done by them. We shall expect that the stimulus of the Pan-American Congress will lead them to make special efforts. There are many things regarding local maladies, local medicinal agents, and modes of treatment which ought to have a great value and interest to the scientific world. Altogether we apprehend that the Pan-American Congress is going to be the most unique, original, fruitful, and interesting of any medical gathering held for a long time.

VOMITING IN FLOATING KIDNEY.

FLOATING kidney may exist without special symptoms and unfavorable results of any kind. On the other hand, through the severity of pain, the inability to work continuously, the gastric and mental complications, and the disturbances in nutrition that these bring about, life may be materially shortened. The dragging pain predisposes to strange fits of melancholy. There is almost always loss of appetite, frequently associated with attacks of vomiting and cardiac palpitation. The neuralgic pains complained of are always on the affected side, and are at times most excruciating in character.

Vomiting as a symptom in this somewhat rare condition deserves special attention. In the *Mercredi Médical*, October 26, 1892, Mathieu reports the occurrence of

vomiting in seven cases of floating kidney that have come under his observation during the past two years. These attacks may come on suddenly, or occur occasionally, and then gradually increase in frequence and severity. At first far apart, they become more and more frequent, and finally result in a complete gastric intolerance. They are often accompanied by severe gastralgic pains, and are analogous in their clinical expression to tabetic crises. The matter ejected may be alimentary, mucous, or biliary. The vomiting is not preceded by nausea, it is projectile, and frequently terminates an attack of gastralgia. The vomiting may last several days or several weeks. These seven cases of Mathieu's were not hysterical, but were decidedly neurasthenic. Their neurasthenia had been brought about by the irritation due to the abnormal motility of the kidney (traction on the duodenum or peritoneum). Besides the vomiting crises, there was also slight dyspepsia, dating from childhood or adolescence, together with constipation and sometimes pallor, more or less emaciation, and mental depression. Occasional causes of this vomiting were menstruation, overwork, and violent emotion.

Careful search should be made for floating kidney in conditions where vomiting constitutes crises. Otherwise serious errors in diagnosis may occur, for such crises suggest tabes dorsalis, pregnancy, intestinal obstruction, hysteria, and poisoning. Then, too, attacks sufficiently similar may occur in neurotic subjects without nephroptosis, in hysterical states and in uncomplicated neurasthenia.

Renal strangulations may take place when floating kidney exists and cause paroxysmal vomiting, There is sudden sharp pain in the abdomen on a level with the displaced kidney, and repeated vomiting. The pulse is feeble and the face is bathed in cold sweat. These phenomena, which may entirely disappear in a few days, are explicable on the ground of strangulation of the kidney in meshes of the subperitoneal cellular tissue, of the deflection or torsion of the hilum, together with obliteration of the renal vein or of the ureter. But it seems well demonstrated to-day that acute hydronephrosis, often intermittent, due to deflection of the hilum, is in reality the condition present. The urine is much diminished during the crisis. Polyuria follows permeability of the ureter. Complete rest in bed is essential, and gastric sedatives should be given, as the chlorhydrate of cocaine. In regard to food, a milk diet in the beginning, with eggs added later, then roast or broiled meats well-cooked and minced, give the best results. In grave cases where there is emaciation and profound depression, gavage of powdered alkalinized meat is necessary. Medical measures failing, the surgeon's work begins. Nephrorrhaphy is in order, a measure that brings about permanent cure in more than one-half of all cases operated upon.

An interesting discussion followed Mathieu's paper (Société Médicale des Hôpitaux). Guyot affirmed that nearly forty years' close observation of floating kidney had failed to reveal to him one single case in which attacks of vomiting occurred. Debove reported one case under observation in 1891. Similar vomiting had come under his observation in hysterical and neurasthenic subjects, and in persons without any neuropathic manifestation whatever. In January, 1889, he had called the attention of the Society to essential gastric crises. Rendu told of a recent case of his own, in which attacks of vomiting, such as Mathieu had described, made him think of serious stomach trouble. Icterus appearing shortly after, his attention was then called to the liver. After consultation with Potain and Bouilly there was question of cholecystotomy. But a floating kidney was discovered before the date of operation. The adverse symptoms disappeared suddenly, for no definite reason, perhaps owing to the passage of a gall-stone. In this particular case the symptoms first led to the consideration of gastric and hepatic disease, before the discovery of nephroptosis. Here Mathieu remarked that iterus has sometimes been noted in floating kidney and has been considered in these cases to bear some relationship to the displacement.

A NEW DEPARTURE IN PHYSICAL DIAGNOSIS.

THERE are very few months in the year when Dr. Benjamin Ward Richardson cannot contribute something interesting to medical science. These contributions are, at times, rather mystic in nomenclature and occult in character, but they show an ingenious and original mind. Dr. Richardson's last opusculum is "intra-thoracic auscultation." He has found that when an œsophageal tube is introduced into the stomach and the open end attached to a stethoscope, sounds from the stomach, heart, and great vessels can be heard and studied. What he found is best described in his own words:

He says: "I could hear soft friction of the tube against the walls of the œsophagus, and was made quite sure that the friction was uniform throughout, and that there was no special constriction or induration in any portion of the tube. When I passed the tube into the cavity of the stomach itself I obtained a sound new to me, like a gentle seething, as of air or gas agitated in a thickish fluid, and at times a gurgling sound of gas, with another sound probably due to muscular contraction of the stomach itself. . . . I withdrew the tube until the opening on the left side came in contact with that portion of the œsophagus that lies in immediate proximity with the heart. By previous auscultation of the heart over the thoracic wall I had failed to detect clearly the two cardiac sounds owing to the feebleness of the cardiac action, but now both sounds were as distinct as they would have been from a normal heart. They were not, however, the same precisely as the sounds we hear through the thoracic wall; they were duller in character, as if they wanted the resonance which is probably produced by the pleura stretched over the thoracic cavity. At the same time they were loud and were singularly distinct. By moving the tube gently up and down I could get the second sound separately from the first, and *vice versâ*; but when I had the opening of the tube midway so as to compass both sounds there was not so much difference between the first and second sound as is common to that distinguishable in ordinary auscultation. I expected that on withdrawing the tube farther out of the œsophagus it would be possible to hear a loud sibilant or vesicular murmur in respiration. In this I was disappointed to a certain extent. It was impossible to catch a murmur, even on a deep inspiration, so distinct as the murmur heard from the chest-wall outside."

Dr. Richardson hopes, by intra-thoracic auscultation, first, to learn about the condition of the stomach. The healthy organ will give its own peculiar sounds; in cancer or other disease these will be modified. Pulsating abdominal tumors can also be heard. Second, the heart-sounds can be studied from another point of view acoustically. Third, thoracic aneurisms can be heard, and, finally, slight strictures of the œsophagus can be recognized. Possibly, pulmonary sounds can be studied also. The fact is recognized that in some sensitive patients the operation of introducing the tube is impossible and that in others it is dangerous.

THE ANTI-CANCER LEAGUE.

Last March a series of letters were sent to physicians and others, with the object of effecting unity of action in regard to the closer study and ultimate extermination of cancer, the scourge of humanity and the shame of medicine. The result is a new organization of scientific and humanitarian interest, known as the Anti-Cancer League, of which Dr. Verneuil, of Paris, is the moving spirit. Its members are prominent medical men, whose object is to attack this dreadful disease in concert and from all directions. The earnest co-operation is desired of all persons engaged in researches in pathology, biology, microbiology, and in veterinary practice and surgery. Explorers and geographers will be asked to obtain facts pertaining to racial and climatic peculiarities in the distribution of cancer, and careful records are asked of each and every country practitioner who is called upon to minister to those suffering from a most painful affection that is as yet incurable. The League has authority to give prizes and substantial aid whenever deserved to those engaged in investigation and to publish records of work done whenever advance is made in knowledge. To-day the organization is in a flourishing condition. The General Secretary is Dr. Paul Reclus, of Paris. The membership fee has been fixed at about four dollars a year. Sixty dollars secures a life membership. Ship surgeons, army medical men, philanthropists everywhere, and the medical press of every nation are all invited to unite in this good work. There is nothing to prevent every country from following the example of France and establishing an anti-cancer league of its own. Pending such universal philanthropic enterprise the French organization deserves aid and encouragement and general recognition as a powerful factor for good.

THE HEALING WATERS OF JAMAICA.

Many of the cities of Europe, it is well known, derive a large part of their revenues from, and indeed owe their very existence in great measure to, the mineral springs in their neighborhood. Balneology has there been developed into a science, with chairs in the universities and special societies devoted to its teaching and advancement, and with journals established solely to record and further its progress. In this country medical men do not, as a rule, look with so much favor on the therapeutic application of nature's ready-made potions, being prejudiced against them, possibly in consequence of the extravagant claims of cure-all properties put forth by the proprietors of certain much-advertised waters. Yet there are few who will deny the healing virtues of some of our better-known springs, and the practice of sending patients during the summer to one or the other of them for a course of the waters is constantly on the increase. Most of our own spas, however, as well as those of Europe, can be visited during a brief period of the year only, and even in those places that are open the year round there is little to tempt the invalid, who finds himself kept a prisoner by the inclement weather during the greater part of his stay, and thus loses the benefit of two great adjuvants in the treatment, namely, fresh air and sunshine.

These reflections have been suggested by the perusal of an interesting brochure on the "Mineral Springs of Jamaica," by the Hon. J. C. Phillipp, M.D., of Kingston. From this we learn that the island, so singularly favored in its mild and equable climate, holds out to the invalid the additional resource of a number of medicinal springs of undoubted therapeutic value. The exact number of springs in the island is unknown, and even those that are known have never been utilized as they should be. This is possibly owing to the fact that the diseases, for the treatment of which these waters would be suitable, are not common among the natives and residents of Jamaica, and it is only within a comparatively recent period that health seekers from the north have begun to avail themselves of the benefits that a winter stay in this genial climate has to offer them. So little attention, indeed, has been paid to these springs that rough analyses have been made of some four or five of them only, and of these but three have been employed at all systematically in the treatment of disease.

The bath of St. Thomas is perhaps the most remarkable of them all. It is a sulphurated sodio-calcic thermal spring, having a temperature of about 130° F. The water resembles in its constituents those of Eaux-Bonnes and Eaux-Chaudes in the Pyrenees, although warmer than the latter, and is found to be useful in the same class of disorders, namely, chronic rheumatic and arthritic troubles, skin diseases, hepatic disorders, neuralgia, bronchitis, incipient phthisis, etc. Another spring, the Milk River Bath, is a sulphurated, alkaline, thermal water, with a temperature of 92° F., and resembling those of Kreuznach, Homburg, and Wiesbaden, except that it also contains a large proportion of sodium sulphate. This has been found to be especially valuable in the treatment of acute and chronic rheumatism and gout. In addition to these there are also chalybeate and alum springs, which do not differ in any essential respect from others of their class in this country and Europe. They all, however, possess the great advantage of being located in a winterless country, where they can be visited and their therapeutic properties utilized at a season when similar resorts in the north are closed to guests.

Some of these Jamaican springs have been improved to a certain extent in that they are provided with bathing facilities and fair accommodation for visitors; but they have never received the attention that their undoubted value would seem to call for. The island government has from time to time made grants for the improvement of certain of the springs, but much more might be done by private enterprise to popularize them. There would, indeed, appear to be an excellent opening here for one or more experienced balneologists who could analyze

these waters and determine their place among the healing springs of the world. If the claims already made for them by practitioners in the island should be sustained by further study of their properties and therapeutic applications, the springs of Jamaica would deserve to rank among the most celebrated spas of the world.

TRY ANOTHER WAY.

THE persistent "specialist in female complaints" to whom we have already twice referred, continues to annoy the greater part of New York's physicians with his frequent consignments of business cards. Our recent advice to tear them into small fragments so as to prevent their dissemination by way of the ash-can and garbage-dumps has failed of its purpose. We are told that thirty thousand of these cards are printed on a standing order every three weeks. We now advise physicians, in and out of town, who suffer this annoyance, to refuse every such package and let them be returned to the sender through the post-office.

A concerted action of this kind would, we think, soon put a stop to the practice.

News of the Week.

A Course of Biological Lectures at Columbia College.—Four courses of lectures will be given by the Department of Biology, in Room 11, Liberty Building of Columbia College, in this city, on successive Thursday evenings, at eight o'clock, beginning November 10, 1892. They are designed for those who desire to keep abreast of the later advances in biology without entering any of the technical courses. The following courses will be given: "History of the Theory of Evolution," by Henry F. Osborn, Sc.D., Da Costa Professor of Biology; "The Cellular Basis of Heredity and Development," by Edmund B. Wilson, Ph.D., Adjunct Professor of Biology; "The Origin and Evolution of the Fishes," by Bashford Dean, Ph.D., Instructor in Biology; "Amphioxus and other Ancestors of the Vertebrates," by Arthur Willey, B.Sc., Tutor in Biology.

New York Academy of Medicine.—At the Anniversary Meeting held on the 17th of November, the hall of the Academy was filled by an audience composed largely of the general public, the ladies being present in greater numbers, perhaps, than even the gentlemen. The usual business was dispensed with, and the President, Dr. A. L. Loomis, introduced the orator of the evening, Dr. Lewis A. Stimson, who had chosen for his subject, "Pasteur's Life and Work in Relation to the Advance of Medical Science." Even the doctors present, whose practice has been so largely modified by the discoveries of Pasteur in relation to the part played by germs in the production of fermentation and disease, and the correlated fact of prevention by inoculation, were led to a clearer understanding of the chemist's work, and made to feel more deeply their obligations for his pains-taking and conscientious industry.

Some Greek Medical Writings.—Our esteemed and learned contemporary, the *Boston Medical and Surgical Journal*, publishes a review of three medical works published in Greek, and dated at Athens B.C. 400, and A.D. 1892. One consists of medical quotations from Aristophanes, another is a treatise on influenza, the third is a hitherto unpublished work of Ætius (A.D. about 400).

The Growth of Dispensaries is so great that a good deal of business push is now required to keep up the record of "philanthropic" work and make the annual reports read well. The establishment of free public baths, the adornment of the waiting-rooms, the creation of night classes and Sunday classes, are the measures which are becoming popular. The time may come when every patient will receive a free lunch and a chromo.

Treatment of Neuroses with Microbic Ferments.—Dr. Lannois, of Lyons, France, in conjunction with Dr. Kohos, has undertaken some experiments in the treatment of chorea and epilepsy by the injection of microbic products. The ferments obtained from staphylococci and streptococci cultures were used. Some amelioration in symptoms was produced, and the experimenters are encouraged to continue.

The Anglo-American Medical Association.—The first meeting of the Anglo-American Medical Association took place on October 14th, and was very well attended by numerous English and American physicians, who are now in Vienna continuing medical study at the General Hospital in various special branches of medicine. The meetings will now be held more frequently than in former years, and it is intended to arrange lectures from time to time, to keep the members informed of the progress of medicine in their native tongue.

Sentenced to a Fortress.—The sentence of Dr. M. Wiederhold, head of a private hospital at Wilhelmshöe near Kassel, to three months' imprisonment, for whipping one of his lady patients, has been commuted by the Emperor into the much less disgraceful one of three months' confinement in a fortress. This act of grace is said to have been actuated by the circumstance that the convict belongs to the military profession as an assistant doctor of the first class.

The Legality of Bequests to Medical Attendants.—In England one hears occasionally of a professional brother having his grief at the loss of a profitable patient by death attenuated by a more or less important legacy bequeathed him by the deceased. In France such a compensation is, in most cases, out of the question, for, by the terms of Provision 909 of the Civil Code, a practitioner is debarred from inheriting from a patient whom he attended during his last fatal illness, provided the will containing the bequest was made during the said illness. It was, however, ruled by the Court of Cassation in 1834 that the above law did not apply to a doctor called merely in consultation.

Mr. Tait as a "Hero."—At the recent Church Congress in London, "the hero of the meeting," to use the words of the Chairman, "was Mr. Tait, toward whom," said the Rev. Canon, "the antivivisectionists assembled felt a certain sort of hero worship. He was *Athanasius contra mundum*, he was an eminent physiologist, and reckoned the most skilful operator in Europe." To appear as the hero worshipped by gentlemen who have indulged so publicly, so largely, and so frequently in reviling and in calumniating many of the most eminent and esteemed

members of his own profession, and to accept from them their homage as the Athanasius fulminating against the medical world, would not, we apprehend, by most medical men be considered an altogether enviable position. But Mr. Tait repaid his complimenters by tacitly accepting the rôle, and further announcing that he appeared "to offer to the British public an apology on behalf of his profession," and that he did so with a sense of degradation which he could not find words to express. That is a form of denunciation worthy of Athanasius, and one which, coming from an eminent physiologist, will not fail to be adequately appreciated by the profession on whose behalf he volunteers to speak, but, unhappily for that profession, with this inexpressible sense of degradation.

A M. Levy has bequeathed to the French Academy of Medicine a sum of 50,000 francs ($10,000), the interest of which is to be handed over every year to the Pasteur Institute, to be applied in the furtherance of researches on diphtheria. The capital sum will be given as a prize to the discoverer of a genuine cure for that disease.

A Pathological Banquet.—At Rome a congratulatory symposium was given to Signor Adolfo Rossi, correspondent of the *Tribuna*, on his safe return from Hamburg, whither he had been sent to report on the outbreak of cholera. The *menu* was intended to give the guests—some fifty in number—a notion of the dangers Signor Rossi had encountered in the discharge of his commission. Here it is: "Recipe—Bacilli virgola al consommé—Pesci dell' Elba in salsa inquinata—Filetto alla 'Stanhope'—Colture di fagiolini—Polli arrosto uso Koch—Gelato algido—Dessert, frutti e disinfezioni a piacere—Infezioni epidermiche di Chianti—Cantanoclismi di Champagne." ℞. Bacilli-virgulæ al consommé—Elbe fish with river sauce—Filet à la "Stanhope"—"Cultures" of *haricots verts*—Roast chickens à la Koch—Ice *frappé*—Dessert: fruits and *dis*infectionery *ad libitum*—Subcutaneous injections of "Chianti"—Champagne imbibed à la Cantani. "In spite of its alarming bill-of-fare, the banquet received ample justice," says the *Tribuna*, which journal seems to think such pleasantries a not ineffectual way of laughing down the tendency to panic which such epidemics evoke among Italians.

The Medical Profession in Australia.—Doctors are in excess in all new countries and all progressive civilization. In Australia, in 1881, there were 1,595 doctors and druggists. In 1891 the number had increased to 3,474. In 1881 the proportion to the population was 1 to 540; in 1891 it was 1 to 328. That there has been a large increase in druggists and quacks is undoubted, but there has also been an abnormal increase in the number of qualified medical practitioners, so that now the number of doctors in the colony is out of all proportion to the population. Victoria, and in fact all Australia, as a field for medical emigration is played out. The large cities are overrun with medical men out of employment, anxious to grasp at anything that offers.

Treatment of Lupus.—Dr. Robinson, of New York, who had found pyoktanin to be without effect in cancer and lupus (*Journal of Cutaneous and Genito-Urinary Diseases*, September, 1892, p. 365), has conceived the idea that such patients should be fed with the flesh and secretions of animals not liable to tuberculosis, as fish, lobsters, etc., and the flesh and milk of goats, upon the theory that the human protoplasm takes on the molecular constitution and properties, to a large extent, of the protoplasm of the organism upon which it feeds. By this course he believes the soil may be made unfavorable for the existence in it of the bacillus of tuberculosis.

Dr. A. Reeves Jackson, of Chicago, died of apoplexy on November 12th. He was one of the founders of the Woman's Hospital, of Chicago, and of the College of Physicians and Surgeons, of which institution he was president when he died.

Decrease of Insanity in the United States.—The census for 1890 shows that the ratio of insane to sane in this country in 1890 was 1 to 620, as against 1 to 615 in 1880.

The Rivista Médico-Quirurgica is the name of a new Spanish medical monthly published in this city, and intended to be the Spanish organ of the Pan-American Medical Congress. It is edited by Dr. Samuel E. Milliken.

The Largest Private Medical Library in the country is said to be that of Dr. N. Senn; it contains about twenty thousand volumes.

A Medical Act Declared Unconstitutional.—The South Dakota medical practice act has been declared unconstitutional on the ground that its title and its contents conflict.

Inconsistency.—The *Chicago Evening Journal* editorially attacks physicians for careless prescription of morphine. It continues, however, to advertise nostrums containing opium, which are more fertile sources of the habit than prescriptions.—*Medical Standard.*

The Cincinnati College of Medicine and Surgery has secured the addition to its faculty of Dr. E. W. Mitchell and Dr. S. P. Kramer. The former will occupy the chair of Materia Medica, while the latter will lecture on Pathology.

The Clinical Journal is the name of a new weekly published in London by E. Knight.

The Chicago Clinical Review is a new journal issued monthly at Chicago, edited by Drs. George Henry Cleveland and Albert I. Beufflem.

Two New Local Anæsthetics.—The muriate of tropacocaine, or tropsin, is a substance obtained from the Java coca, and said by Professor Schweiger to have a local anæsthetic action resembling that of cocaine. It is weaker in action, but it causes anæsthesia more rapidly. Eugenol-acetamide is recommended as a new anæsthetic. As crystallized from water it occurs in lustrous scales; from alcohol in fine needles; melting at 110° F.

This compound, when applied in the form of a fine powder, produces local anæsthesia, without any caustic action, similar to cocaine. This anæsthetic effect, in connection with the strong antiseptic properties of eugenol-acetic acid, secures a place for this new amide in the treatment of wounds.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, November 14, 1892.

JOSEPH D. BRYANT, M.D., CHAIRMAN.

Congenital Dislocation of Both Hips.—DR. W. W. VAN ARSDALE presented a girl, five years old, who began to walk at two years and a half, showed a waddling gait, which she still had, and which was due to congenital dislocation at both hip joints.

New Instrument for Treating Inguinal Hernia.—DR DALLAS presented the instrument. It was made to push down the inguinal canal through a transverse slit just below the external ring, and when passed down a metallic scabbard was partly withdrawn, exposing numerous fine needle projections on the upper and lower side near the triangular and smooth point—the needles covering a rectangular area measuring about one-third of an inch on its longer side. When the instrument was withdrawn from the canal, these fine projections freshened the upper and lower surfaces, the cord being pushed out of the way, and protected by a groove at one side of the instrument. The transverse slit for entrance was then sealed, a compress was applied, and the canal became obliterated by the adhesion of the freshened surfaces. A truss was worn, at least for some months, as a safeguard. Local anæsthesia with cocaine was used. Recent herniæ could thus be cured; old ones made tolerable. There was no reaction. The method could be applied to femoral herniæ also.

Spasmodic Torticollis.—DR. REGINALD H. SAYRE presented a healthy-appearing young man, whose head was drawn to the left, at nearly a right angle to the body, by spasmodic contractions of the muscles of the neck on that side. The condition began five years before, and had gradually grown worse, although he was not as bad when presented as he had been last spring, when he was unable even to sleep without morphine. At present the head remained quiet during sleep, the squirming movements were not present during swimming, and were only slight when he rode a bicycle. Dr. Sayre proposed to treat him by gelsemium, conium, and similar drugs, put him to bed, and make traction upon the head, and, failing, to resect three or four of the first cervical nerves. The pathology was not clear to him nor to the neurologists who had seen the case. Dr. Keene had reported two, and Dr. Powers one case.

Lesions of the Appendix Vermiformis and Cæcum Demanding Surgical Interference; Report of Recent Cases, with Deductions.—DR. JOHN A. WYETH read a brief paper on this subject, and presented illustrative cases. The anatomical position of the cæcum rendered this part liable to injury. The appendix, having little peristaltic power, fecal or other matter entering it was not likely to be thrown out again. Ulcers might form, perforation might take place, escape of gas or solid contents might ensue, or without perforation inflammation might be set up and involve parts immediately about. Pressure might interfere with nutrition, and lead to breaking down, or a similar effect be caused by pressure from generation of gas by decomposing matter. Pressure was greatest in the sitting posture, which made sedentary occupations more dangerous. A mild catarrhal condition might extend and involve the general peritoneum. Gangrene might develop quickly, in which process pressure might play an important rôle. In the light of the facts named it was easy to account for a slow process in one case, and sudden collapse in another, with intermediate grades.

Catarrhal appendicitis was the simplest and most innocent variety. The symptoms varied with the intensity of the catarrhal process and with its recurrence. Usually the pain was mild, fever not present, tumefaction or local abdominal resistance absent. When the entire wall became involved, and inflammation of the peritoneum commenced, pain and sensitiveness became more prominent. Abdominal resistance showed that there was an adhesive process set up to hedge in the inflammatory exudate or pus. General gangrene of the appendix was the most formidable of all the lesions; death might ensue within a few hours, even before rupture. In local gangrene and ulceration general peritonitis might be prevented by fortunate early adhesions, but usually when perforation took place it was sudden enough to permit escape of gas or contents, and lead rapidly to general peritonitis. Lodgement of foreign particles might produce mild inflammation and adhesion, and at last abscess.

The cases which he related were nine in number, treated during four weeks in September last. Seven were operated upon, one refused an operation, and in the other he declined to interfere because the patient was already in a moribund condition.

Case I., recurrent appendicitis, absorption of the inflammatory product in six attacks; the patient sustained an injury over the cæcum when the seventh attack developed, with formation of a large abscess which opened into the rectum. Dr. Wyeth cut down in the right iliac region and removed pus and the diseased tissues, which was always necessary in order to place the patient in safety for future recovery.

Case II., one of acute appendicitis, acute circumscribed abscess, evacuation by a colleague through a posterior incision, resulting in fecal fistula, recurrence of symptoms; second operation made by Dr. Wyeth by laparotomy, removal of the appendix and abscess-wall; cure. It was safe to say that this patient was now absolutely guaranteed against the dangers of a broken-down appendix, and he thought no other procedure except a radical one should have been employed on the first occasion.

Case III. was the one in which he refused to operate because the man was already moribund when he was called. There was acute perforative appendicitis with foci of suppuration found at autopsy. The mistake in the case was on the part of the general practitioner not being ready to operate at once, instead of delaying to send for a surgeon, for the man's chances of life were lost after the first few hours following perforation. The possibility of adhesive inflammation shutting off the opening was very slight. If the man should recover without operation he would be continually exposed to future attacks.

Case IV. was one of acute gangrene with rupture of the appendix, rapid formation of lymph, only partly shutting off escape of fecal contents; operation; removal of the appendix and abscess-wall; recovery.

Case V. was one of acute gangrene and rupture of the appendix, rapid enclosure of the diseased area by adhesions; removal of diseased structure; recovery. The patient was eight years of age, the operation was done thirty-nine hours after the first pain, yet he found an abscess as large as one's fist.

Case VI. occurred in a girl, aged five, whose attack began some days before he saw her and operated. Her appearance was that of a person suffering from general sepsis. He opened into an abscess, washed it out, put in gauze, and she recovered. The two cases were contrasted: the boy was operated upon at once and a radical cure by removal of the abscess and appendix was effected; in the case of the girl, five days had elapsed with the existence of a large abscess, high fever, great suffering, and greater danger of rupture and death. When the operation was finally done the child was too far gone to stand a radical procedure and the focus of abscess was still present.

Case VII. was one in which the general peritoneum was shut off from the abscess; he opened anteriorly into the peritoneum, could look down and locate the abscess exactly, then cut near the crest of the ilium and evacuated it extra-peritoneally.

Case VIII. was one in which he evacuated the abscess in the iliac region, but made another incision in the median to learn the condition of the peritoneum, and was able to exclude infection of that membrane. The inflammatory process was too far advanced in this case to make radical operation safe. The patient recovered.

Case IX. was one of acute inflammatory appendicitis, but a physician advised against an operation and the patient recovered. It remained to be seen, however, whether the physician or surgeon was the better adviser.

Dr. Wyeth usually employed chloroform anæsthesia, advised opening the peritoneum in the median line either in locating the tumor exactly, or after the extra-peritoneal incision, for the purpose of excluding or detecting sepsis; the appendix and abscess should be extirpated radically if possible; the surrounding cavity was protected during the operation by gauze; he touched the stump of the appendix after removal with a point of bichloride of mercury; the temperature usually was between 100° and 103° F.

Dr B. F. Curtis presented a man whom he saw in his second attack of appendicitis. The appendix was perforated, there were two abscesses, and the cæcum was found when separated from the iliac fossa perforated in two places. Two openings were made into the abdominal walls during the operation. The appendix was removed, the openings in the gut closed, the abdominal wounds healed, and the man had since remained well.

Dr. Curtis also presented a man who had been operated upon outside the hospital, and when he saw him in the hospital he was in an exhausted condition; there were two openings, one leading into an abscess cavity at the cæcal region, the other situated anteriorly, leading into the gut, evidently low down, and discharging fæces. He sewed up the fecal fistula, but it did not entirely heal for a time; he made an opening farther back for drainage of the abscess and closed the existing wound; two abscesses formed in succession below the umbilicus, but finally all the wounds had closed. This patient required first to be built up before operative interference was instituted.

Dr. Curtis thought that in the majority of cases after the tenth day, and even after the third or fourth day, a simple incision into the abscess would be followed by recovery. He would not only limit radical operation, or search for the appendix and its removal, with that of the abscess-walls, to cases in which the patient was in good condition, as Dr. Wyeth had done, but also to cases in which it did not require great interference, with danger of sepsis and peritonitis and a prolonged operation.

The Medical Side.—Dr E G. Janeway said with regard to the propriety of an early operation that if the subject were in good general health and a mass could be easily made out, he would not, at the present time, hesitate about recommending an early operation. But one saw a good many cases which made him hesitate. There were many difficulties surrounding the subject. First, the difficulties of diagnosis, which were considerable. Within a year he had been asked to see cases of appendicitis in which he found, instead, pneumonia, or empyema, or intercostal neuralgia; the pain was referred to the right iliac region. Then there were cases of appendicitis mistaken for something else, because the pain was not in the usual situation, perhaps higher, to be explained possibly by adhesions of the omentum. Renal colic had simulated and been mistaken for appendicitis. One could not be guided by fever, as any pain might cause some elevation of the temperature. Lumbo-abdominal neuralgia had been mistaken for appendicitis and led to operation. He had known a surgeon to cut down for appendicitis and find an ovarian abscess. He had known peritonitis to be found, but no appendicitis or other known cause. Dr. McBurney had suggested as the origin of such obscure cases perforation by a pin. It was difficult, too, to say whether one had a general or local peritonitis, and if general, whether it was septic or simple. There might be local paralysis of the intestine, causing obstruction; opium might have been given and produced paralysis. He knew nothing more difficult under these many conditions than to say whether one should or should not operate. He had known three cases within a year go without operation because their state was too low or they had rejected interference, and all got well. He had known few cases to recover after operation for rapid general peritonitis following perforation. An early operation in selected cases was a judicious and wise measure. If he thought there were not yet sepsis, and the patient's pulse and general state were not favorable, he would caution delay.

Dr. Van Valzah had seen twenty-five recurrent cases but only five in the acute attack, and all recovered without an operation. Perhaps they were mild cases, or were not appendicitis, but cæcitis or perityphlitis, as he was disposed to recognize these different forms. The treatment had been medicinal, usually repeated doses of Epsom salt until free action of the bowel took place, antifebrine or antipyrine if fever were present, opium if great pain, no food, or only one feeding in the twenty-four hours, perfect quiet, thorough "splinting" of the seat of inflammation. To prevent recurrence, he gave the patients such food as they could appropriate, strengthened the nerves, avoided constipation, perhaps applied electricity locally to the muscles.

Dr. F. A. Castle exhibited an enlarged diagram from a small, almost unknown, but valuable book of H. R. Sylvester, in which he sought to prove that the alimentary tract was homologous except at the small intestine, the only remains of the right half here being the appendix vermiformis; the symmetry was resumed at the cæcum.

Dr. Fowler, of Brooklyn, had operated in 150 cases for appendicitis, and expressed the view that Dr. Janeway must have had so much difficulty in diagnosis because opium or other drugs had been given before he saw the cases.

Dr. Janeway interrupted him to say that he had only mentioned the diagnosis which had been made before he was called.

Dr. Fowler thought the diagnosis, as a rule, was not difficult. Perityphlitis and cæcitis meant in reality appendicitis. It was true the pain might be located in an unusual situation. In three of his cases it was on the left side. In five cases he had opened the abdomen in search of appendicitis and found some other condition: in one pyosalpinx, in two a neoplasm, in one ruptured gall-bladder, in one obstruction of the intestine. In all of these the pain was over the cæcum. Gangrenous ulceration of the appendix was liable to invade the iliac vessels. He did not think it good policy where there was a large abscess to make prolonged search for the appendix.

Dr. Willy Meyer believed in operating early. The past summer he had been called to operate in a case, but the symptoms were then mild, and he told the physician he would wait, but hold himself in readiness in case the symptoms should become worse. He was sent for only about two days later, operated, but it was too late, and the man died. He referred also to a case in which renal colic was mistaken for appendicitis.

Dr. Lewis emphasized the possibility of the appendix being well back in the abdominal cavity.

The Chairman mentioned the location of the appendix found at autopsies at Bellevue. The facts would appear in a paper soon.

Dr. Wyeth said, in closing, that he also thought cases should be selected with care, but usually for operation. If all of a thousand suspected cases were operated upon the mortality would be probably fifty per cent. less than in another thousand cases which physicians now would let pass without an operation.

Probes and Probing.—Dr. John H. Girdner, in a paper with this title, showed the reasons for failure with ordinary probes, and then described and demonstrated

the advantages of the telephonic probe. The Bell Telephone Company had at last given a firm permission to manufacture it for use by the profession. No battery was required. The instrument consisted of a telephone receiver; to this two wires were attached, about three feet long; at the other end of one wire was an aluminium bulb which the patient held in his buccal cavity; to the other wire the probe was attached, composed of aluminium, steel, or other metal different from the bullet or metal of whatever kind being probed for. As soon as this was touched by the probe a click was heard. Esmarch had pronounced the instrument an ideal one, and it had been introduced throughout the German army.

Dr. Fowler said he had used the telephonic probe with much satisfaction, connecting it with the ordinary telephone receiver in his office An officer wounded at Bull Run had had the bullet extracted from his arm, yet a sinus had continued for years and could not be healed, and surgeons had been unable to find any foreign obstacle. The telephonic probe revealed at once a piece of tin, which he took out, and the arm was soon perfectly well.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, November 4, 1892.

Charles L. Dana, M D., President, in the Chair.

Thiersch's Skin-Grafting for Webbed Fingers.—Dr. Robert Abbe presented a child, aged a year and a half, all of whose fingers of the right hand were webbed together so that it presented the appearance of a mitten, the fingers also being congenitally lacking in one phalanx. The case was specially interesting as illustrating the successful application of skin-grafting to the correction of this congenital deformity. A clean incision separated each finger from its neighbor, and a long skin-graft was applied continuously to the raw surface down one side and up the other in each cleft. On account of the inability of satisfactorily dressing so small a child's hand every day without disturbing the grafts, Dr. Abbe applied a plaster-dressing to the entire hand and forearm, and even above the elbow, thus immobilizing the fingers. The skin-grafts were untouched for two entire weeks; at the end of that time the raw surfaces were found absolutely healed by the grafts, without a point of granulation.

Partial Laryngectomy for Extensive Carcinoma.—The second case presented by Dr. Abbe illustrated most excellent results from the almost complete removal of the larynx for extensive carcinoma. The patient was a man, forty-five years of age; had been treated more than a year before by Dr. French, of Brooklyn, for papillomatous vocal chord; subsequently came under the care of Dr. Rice, of this city, who found extensive carcinoma involving more than half the interior of the larynx, and a few days before the operation the patient was referred to Dr. Abbe for acute obstruction with œdema above the cancer. Being in otherwise good condition, tracheotomy and laryngotomy were combined, the entire thyroid cartilage, except the posterior third of the right ala, was removed, together with all the larynx, except a strip of the posterior wall, one-half inch in width, continuous with the bronchial mucous membrane. Part of the cricoid cartilage was invaded, and also removed. The wound was packed lightly with iodoform gauze; the patient, fed for ten days by soft catheter, made an uninterrupted recovery, and ate solid food at the end of two weeks without its falling into the larynx. An attempt had been made to use a Gussenbauer artificial larynx, but the patient was unable to wear it on account of pharyngeal irritation and nausea. Moreover, it was found that with a large tracheotomy tube, which he now wears, he can, by closing the front with his finger, articulate well, though with hoarse guttural sounds, so as to be heard distinctly by an audience of a hundred.

Dr. Andrew H. Smith remarked that the case of laryngectomy showed the best result he had ever seen, and illustrated how the speaking apparatus can adapt itself so as to give distinct phonation with even imperfect sound.

Regarding the skin-graft case, The President said that webbed fingers were thought by recent observers to be a sign of a degenerative type of individuals, but that he had not been able to find corroborative proof. Other members were unable to recall any association of defective intellect or body with this deformity.

Central Glioma of the Cord, with Hemorrhage Within.—The President presented two specimen cords. The first was a case of central glioma and hemorrhage within. The case was of historic value. He had seen the patient (he was a man, aged forty-five) two years before, with a history of spinal trouble supposed to be transverse myelitis. The man partly recovered from pain in his legs. He had exaggerated reflexes and other signs of transverse myelitis. He left the hospital and returned about two weeks ago with a history of agonizing pain around his body, paraplegia, anæsthesia, atony of the bladder, but no fever. He died exhausted by his pain. The autopsy revealed in the middle part of the cord a fusiform enlargement, which was found filled with clot running up and down the cornua for four or five inches in one horn.

The dura, externally, and pia were normal. The fusiform enlargement extended for three inches. The history seemed to show a repetition of the former condition of the pain. The diagnosis was originally probably glioma, with hemorrhage and enlargement; secondarily, a repetition of the hemorrhage, and death. It was unusual, because hemorrhage of the cord was regarded ordinarily as not painful.

Locomotor Ataxia; Specimen.—The second specimen presented by The President was a marked illustration of the spinal cord in the third stage of locomotor ataxia—a man, aged forty-six, eleven years ill, and in the third stage three years before death. He presented a characteristic picture of a man with locomotor ataxia and crisis.

Dr. Beverley Robinson asked if neurologists had given up the stretching treatment.

The President said he still used it occasionally, but in old cases. The patients thought that the bladder was better, and that they walked better for a while, and the treatment was repeated every few weeks or months. Some cases had shown remarkable relief undoubtedly. He only used it in late second stage. It was still used at the Salpetrière (Charcot), but it had been given up in London, Berlin, and Washington. Modifications of the French method were worthless.

Food In Fevers; Is it not Unnecessary that it be Restricted to Fluids?—Dr. George L. Peabody opened the discussion (see p. 620).

Dr. Andrew H. Smith thought we had prolonged typhoid fever cases at times by too gentle a diet. He recalled cases of typhoid kept on a very low diet that were restored by more liberal food in three days. He recalled the case of a woman who had prolonged convalescence, with persistent low typhoid for three weeks, whom the doctor had ordered to be fed, but whose husband had taken outside counsel of friends on Wall Street not to give solid food too soon, and the consequence was prolonged convalescence. Dr. Smith did not think we discriminated with regard to food sufficiently; that is, we gave irritating and fermenting food. We all had also a nameless dread of harsh food scraping the ulcerated surface, whereas there was hardly any food that we could give that would have that degree of solidity that would produce much harshness when it reached the ulcers in the bowels. He endorsed Dr. Peabody's statement of the raw milk curds being irritating, and he had seen the rectum packed with the remains of milk-curds. Dr. Musser, of Philadelphia, had called attention, in a recent number of the *Journal of the American Medical Sciences*, to prolonged types of typhoid convalescence from poor feeding. Dr. Smith advised the cautious use of more food. The large quantity of milk used to get a good amount of nutrition

diluted the digestive juices to such an extent that they were inferior solvents.

Dr. Beverley Robinson recalled two cases of typhoid with hemorrhage in which he had examined the stools and found the milk-curds—one where non-peptonized milk was used and the curds were large; the second where peptonized milk had been used, the curd particles being small. He thought bouillon, beaten egg, and wine-jelly should be freely used. Milk, he thought, was not good because of the curds. We should be guided by the patient's feeling of hunger. Stress should be laid on the removal of excreta from the bowels, and this was quite as important as the question of food.

Dr. J. West Roosevelt thought a prolonged milk diet prolonged the fever. Records of cases of typhoid, running say four weeks, were apt to show a changing type of continued fever; then, when such cases had the fluid diet stopped and were given stale bread and fine meat, the temperature dropped and convalescence set in. He never could understand why we feared small solid food effects on ulcers. An important observation of Fothergill's was recalled, that we were apt to get our prolonged fever cases in a final scorbutic state. A hungry patient, was, as it were, in pain. If we relieved his pain, we checked his fever. Speaking of some patients not bearing milk well, Dr. Roosevelt had lately a striking case in which cow's milk acted as a poison. This baby had been brought up on fruits, cereals, etc.

Dr. Abbe endorsed the disposition to increase the food in low fevers, according to the toleration of the stomach. He had found, besides the usual peptonized milk, four articles that had served him well—chocolate, scraped meat, baked potatoes, and junket. He did not believe that any of these, after leaving the stomach, could be accused of irritating ulcers of typhoid fever.

Dr Bacon, of New Haven, present by invitation, wished to add his endorsement to Dr. Peabody's ideas. In the treatment of fever he believed the use of solid food was well illustrated in the case of yellow fever, with which he had a large experience. He had found it often not possible to get milk in hot climates, and he believed we had no more right to disregard the patient's appetite in yellow fever than in phthisis, so also in typhoid. Comparing the typhoid patients he had kept on a milk diet strictly with those whose food had been reasonably varied, he had been struck with the better general condition of the latter class.

Dr. William M. Polk referred to the former habit of preparing patients for abdominal operations by keeping them on milk for forty-eight hours, and then for ten days afterward, and the results were often disastrous. The results formerly attributed to shock and sepsis he believed to have been due sometimes to starvation. Now, in a varied diet he rarely saw such cases of exhaustion as formerly were common in grave surgical operations. Now solid food was given to those who had an appetite for it.

The President said that most of us did not give solid food for fear of causing irritation and hemorrhage, or perforation. He would like to ask Dr. Peabody whether he had had experience bearing on this subject. It was affirmed also in typhoid that a drop of blood contained more corpuscles than in health, and in convalescence there was a less number of corpuscles; in other words, patients suffered from lack of water, and it was supposed that a constant fluid diet was therefore desirable.

Dr. Peabody, in answer, said that Dr. Henry, of Philadelphia, had affirmed that there was a deficient amount of water in the system, illustrated by the relatively larger number of corpuscles in a drop of blood, and that hence an abundant fluid diet should be given. As to hemorrhage or perforation from injudicious feeding, he thought we were still in the dark.

Orchitis is mentioned by an English writer as one of the manifestations of influenza.

Correspondence.

LEPROSY AND SYPHILIS.

To the Editor of the Medical Record.

Sir: An article in the Medical Record of September 10, 1892, on "The Etiology of Leprosy," by Dr. George L. Fitch, of San Francisco, challenges criticism by reason of his identification of this disease with syphilis. He regards it as "a fourth stage of syphilis, which stage occurs epidemically in races virgin to syphilis, or sporadically in persons whose systems have reverted to a condition virgin to the disease, and occurring also in those presenting a distinct neurotic taint, and whose habits have been such—in regard to food-supply and manner of living—as would, without the before-stated conditions, produce ordinary scrofula."

My purpose here is to give some reasons why this theory is untenable.

The only argument adduced in its favor is the occasional sequence of syphilis by leprosy in the same person, and especially the extraordinary ravages of leprosy among the aborigines of the Hawaiian Islands, together with the general prevalence of syphilis, both appearing since the discovery of the islands in 1778.

It is to be observed that Dr. Fitch strenuously denies the contagiousness of leprosy, even by its inoculation; but he does not attempt to explain how or why syphilis lost this eminent property of contagiousness between the third and fourth stages, for it is known to be communicable in every stage generally included under this name. He does not deny the strong hereditary tendency of syphilis, nor explain why this property is nearly or totally lost in the stage of leprosy.

It is of general acceptance, Dr. Fitch being no exception, that a syphilitic subject is not capable of a new infection of the disease. His own failures to inoculate syphilis on Hawaiian lepers is to be explained by their being already syphilitic, in common with the majority of their countrymen. On the other hand, Dr. M. Hagan, who has resided on those islands, declares: "It has been settled beyond dispute that a leper will contract syphilis and recover from it with proper treatment, while the original disease goes on and ends in death." Dr. Robson Roose ("Leprosy and its Prevention," p.76), remarks that lepers not unfrequently contract syphilis. Kaposi, in 1889, reported a man afflicted at the same time with syphilis and leprosy, the initial appearance of leprosy antedating that of syphilis.

Antisyphilitic remedies have no control of leprosy; on the contrary, mercury and potassium iodide have been found injurious. At the same time the remedies which have gained some credit in the treatment of leprosy are totally inert in syphilis.

It is a well-known historical fact that syphilis, as a constitutional disease, was as much a stranger to Europe in 1490 as cholera was in 1825. The ravages of syphilis in Europe during the first half of the sixteenth century were a true counterpart to those of the same disease in the Hawaiian Islands three hundred years later; but mark the distinction. Leprosy, one of the oldest diseases known, was declining throughout Europe when syphilis made its appearance, and it has never revived since. It has survived in many localities—notably so in Western Norway, where syphilis has been less prevalent than in Southern Europe.

The bacillus leprae is now generally recognized by pathologists as peculiar to leprosy and inseparable from it. It has never been found in syphilitic growths, though several micrococci have been observed and gained more or less credit as factors in causation.

To my mind these considerations greatly outweigh the sole argument of Dr. Fitch. Indeed, a single example of syphilis following leprosy in the same individual destroys his theory.

H. S. Orme, M.D.

175 North Spring Street,
Los Angeles, Cal.

DIGITALIS IN KIDNEY DISEASE.

To the Editor of the Medical Record.

Sir: I was not a little surprised to read in the Record of November 5th a short article on "Digitalis in Kidney Disease," "Huchard has recently advanced the idea that digitalis, even in large doses, is not hurtful in affections of the kidney," etc.

Ever since I have known anything of medicine I have so used digitalis, and I believe with marked benefit to patients. My authority for so using it was Professor A. L. Loomis. Dr. Huchard need not have brought the matter forward now as anything new if he had read "Diseases of the Respiratory Organs, Heart, and Kidneys," by Professor A. L. Loomis. Neither do I see anything new as to the manner of administering the drug, since large doses are specified both in the book I mention, published in 1875, and in this recent article.

Yours respectfully,

W. Washburn, M.D.

42 Irving Place.

MERCURY IN CHOLERA.

To the Editor of the Medical Record.

Sir: With reference to the statement by Dr. Vanderpoel of his success in the treatment of cholera with calomel and camphor in 1832, reported in the issue of the Medical Record for October 22, 1892, I recall an also held that it was un[illegible]M.D. of Concordia, La., which sions to which this article gave rise lasted an entire year, and then the majority of the members of the Academy, while unwilling to condemn M. Villemin, yet refused to accept his views concerning the unity and the contagiousness of tuberculosis. He had the privilege, which is not accorded to every man, of living to witness his own triumph.

Swallowed a Tooth.—A writer in the *Deutsche Monatschrift für Zahnheilkunde* reports the case of a domestic who, while taking a drink of water, swallowed a false tooth which had been held in position by a metal plate. All efforts to extract the tooth failed, and the woman died of hemorrhage a few days later. At the autopsy it was found that the plate had caused a perforation of the œsophagus just above the entrance to the stomach.

Dr. Dabbs, Tennyson's physician during his last illness, is a dramatic writer as well as physician. He has written several plays, which are said to possess considerable merit, and has also written some very good poetry.

A New Street Danger.—The improvement in the paving of New York streets has given a great impetus to bicycling in this city, and has at the same time added to the dangers which pedestrians have to face in crossing the streets at night. People are knocked down by the silent wheel daily, and recently a noted lady violinist was thrown down and barely escaped a fracture of her arm. We have no wish to repress bicycling, but it should be regulated in some way and made less of a menace to life and limb.

Germ-free Water.—Drs. V. and A. Babes have made a number of experiments to determine the best method of purifying water for drinking purposes (*Centralblatt für Bacteriologie*, July 30, 1892). Filtration, they claim, is not only useless as far as removing the micro-organisms is concerned, but actually favors bacterial growth. Alum has been found by them the best, not only for clarifying water, but also for purifying it. Powdered alum is added to water, which is then well shaken and allowed to stand twenty-four hours in a cool place. At the end of this time the water is not only clear but quite free from germs. The addition of alum in large quantity is harmful since it leads to digestive disturbances. About ten grains to the gallon is amply sufficient to accomplish the desired end. After four or five days' use the vessel is emptied, washed out with sterilized water, and refilled.

appearance there on February 23d. It assumed a very grave character from its commencement, almost every case proving fatal, notwithstanding that every plan of treatment was resorted to. I have tried," he adds, "the prophylactic powers of mercurial salivation in a few cases; these were not attacked by cholera."

A paper had appeared in the *New Orleans Medical Journal* for November, 1849, in which reference is made to a number of negroes who had been "intemperately salivated" previously for some chronic intestinal affection; these escaped attacks, though numerous others were seized and died.

The correspondent continues: "My plan is, as soon as cholera appears among the people, to salivate them and keep them under the gentle influence of the medicine as long as the disease continues. This time," he says, "does not extend beyond two or three weeks."

This is a severe expedient, but the several relations go to show that mercury may be an efficient remedy in cholera, and it very probably acts by destroying the germs, as well as by its modifying influence upon the viscera involved. If this be true, it is only an additional proof of the utility of mercury in the initial stages of many diseases affecting the intestinal canal, as well as in others involving the general system.

F. Peyre Porcher, M.D.

"DOES SHE DO IT?"

To the Editor of the Medical Record.

Sir: The answer to a query in the Medical Record of recent date was, I think, given in the admirable paper on "Typhoid Fever in Chicago," published by Professor Sedgwick and Mr. Allen Hagen in the *Journal of Engineering News*, April 21, 1892. The reported death-rate of 17 per 1,000 is very decidedly misleading, and does not at all suggest the existence of a serious epidemic of typhoid fever which is now prevailing in that great city. Neither does the death rate of Chicago give the faintest suggestion that hundreds who toil in that unhealthy city sicken and die at their homes in the many towns within an hour or two railway distance from their places of employment. Besides all this, thousands are continually passing through Chicago and drink the foul and deadly water of the lake in railway cars, hotels, and restaurants, and are taken sick when hundreds of miles distant from the source of the infection.

A city with wooden pavements, very much neglected and ready to increase the insanitary condition of the city in an alarming extent, with a poisonous water supply, with foul odors from the immense slaughter-houses, with the air filled with smoke from the great chimneys, with the worst milk supply of any American city, with poor and expensive food supplies, and with a life of "hustling" for an existence, it is very unreasonable to assert that the 17 in 1,000 gives any truthful estimate of the death-rate caused by residence, whether transient or permanent, in Chicago.

It seems to be the opinion of very many that the truth should be concealed, lest any fears might be created which would act injuriously upon the success of the World's Fair. This is an astonishing position for hygienists to be willing to occupy.

The whole truth, and nothing but the truth, is what the public have a right to expect.

Professor Sedgwick's paper throws valuable light on this subject, and is a truthful exposition of sanitary, or whether insanitary, conditions obtaining in Chicago to-day.

W. Thornton Parker, M.D.

Beverly, Mass., November 20, 1892.

An Early Sanitarian.—Cyrus was a wise leader, and, it would seem, pretty sound also on health matters. It is reported of him, when crossing the Choaspes, that he had all the water used for drinking purposes first boiled in silver bowls.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 19, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	37	7
Scarlet fever	83	10
Cerebro-spinal meningitis	0	3
Measles	49	7
Diphtheria	97	30
Small-pox	6	0
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

A Bust of Dr. Guillotin is to be erected at Versailles. In the paragraph in which this is announced it is carefully explained that this memorial is not erected for the invention of the guillotine, nor because the doctor was Professor of Anatomy, Pathology, and Physiology at the Faculty of Medicine of Paris, was a *savant* of high reputation, a philosopher, a reformer, and a good man in every acceptation of the term—not on account of all these virtues, but because he moved the resolution that the *tiers-état* when expelled from the hall of the States-General, should hold their meeting in the tennis-court.—*Provincial Medical Journal.*

Running Through Many Editions.—*The Medical Press* is responsible for the statement that a certain medical author, in order to insure success in the eyes of the uninitiated, printed one thousand copies of a book, of each fifty of which he had a different "edition" printed so that by the time the last fifty were drawn upon the book had reached its twentieth edition.

The City of Dublin Hospital having proved inadequate to accommodate the numerous applicants, the Board have determined to erect a structure which will about double the present accommodation. An excellent design has been selected and estimates made, showing that a hospital according to the plans adopted may be constructed at a cost of from £9,000 to £10,000.

To Prevent the Spread of Infection.—The city authorities of Detroit have passed the following ordinance to prevent the spread of infectious diseases. The English is a little difficult, but there seems to be some sense in the ordinance. "Every physician having a small pox, variloid, typhus fever, Asiatic cholera, glanders, erysipelas, diphtheria, scarlet fever patient, or any other contagious disease, dangerous to the public health, during each and every visit to the same, shall exercise all the precaution known to the profession. Every undertaker having in charge the body of any person who has died of either of the above-mentioned diseases shall, during the time he is preparing such body for burial, wear a long rubber overcoat buttoned to the chin, and after he has properly prepared the body, shall spray his hair, beard, hands, and boots, especially the soles, with disinfectant cologne, and shall wear his rubber coat when carrying and or arranging said coffin or casket during the funeral. After said funeral the undertaker shall spray his hair, beard, hands boots or shoes and rubber coat with said disinfecting cologne before returning home or walking the public streets. Any person nursing or taking care of any person sick with either of said diseases shall, before going upon the street or visiting any other house, take a warm bath, and disinfect the hair of the head, the hands, the finger-nails, by means of the above-mentioned spray, changing all underclothing and clothing which had been worn while in attendance on the patient, and see that the former underclothing and clothing are thoroughly disinfected by either sulphur, boiling in water, steam or spraying with disinfectant cologne, and allowed to dry, and shall not attend any non-contagious disease without a permit from the health officer. Every clergyman conducting burial service over the body of any person dying of either of said diseases shall observe the regulations given above for physicians."

Yellow Fever at Santos.—Reports from Santos, Brazil, to a Philadelphia merchant, reveal a sad story of yellow fever at that important seaport in South America. An epidemic has been raging there for months, and the dead have been piled in trenches of great length. It is claimed that more victims have been swept away in and around Santos than have died in Central Europe from the cholera. Three hundred and forty-seven vessels are awaiting their turn to discharge valuable cargoes shipped from all parts of the world, and it is claimed they will be there a year hence, still waiting to be towed alongside the discharge berth.—*Philadelphia Record.*

The Residence of the Late Sir Morell Mackenzie, in Harley Street, is still advertised for sale. It was thought that the house would be snapped up immediately it came into the market by some enterprising throat-specialist, but throat specialism is rather at a discount just now, the novelty of the usual throat medicaments having worn off. —*Hospital Gazette.*

---

property or contagiousness between the third and fourth stages, for it is known to be communicable in every stage generally included under this name. He does not deny the strong hereditary tendency of syphilis, nor explain why this property is nearly or totally lost in the stage of leprosy.

It is of general acceptance, Dr. Fitch being no exception, that a syphilitic subject is not capable of a new infection of the disease. His own failures to inoculate syphilis on Hawaiian lepers is to be explained by their being already syphilitic, in common with the majority of their countrymen. On the other hand, Dr. M. Hagan, who has resided on those islands, declares: "It has been settled beyond dispute that a leper will contract syphilis and recover from it with proper treatment, while the original disease goes on and ends in death." Dr. Robson Roose ("Leprosy and its Prevention," p. 76), remarks that lepers not unfrequently contract syphilis. Kaposi, in 1889, reported a man afflicted at the same time with syphilis and leprosy, the initial appearance of leprosy antedating that of syphilis.

Antisyphilitic remedies have no control of leprosy; on the contrary, mercury and potassium iodide have been found injurious. At the same time the remedies which have gained some credit in the treatment of leprosy are totally inert in syphilis.

It is a well-known historical fact that syphilis, as a constitutional disease, was as much a stranger to Europe in 1490 as cholera was in 1825. The ravages of syphilis in Europe during the first half of the sixteenth century were a true counterpart to those of the same disease in the Hawaiian Islands three hundred years later; but mark the distinction. Leprosy, one of the oldest diseases known, was declining throughout Europe when syphilis made its appearance, and it has never revived since. It has survived in many localities—notably so in Western Norway, where syphilis has been less prevalent than in Southern Europe.

The bacillus lepræ is now generally recognized by pathologists as peculiar to leprosy and inseparable from it. It has never been found in syphilitic growths, though several micrococci have been observed and gained more or less credit as factors in causation.

To my mind these considerations greatly outweigh the sole argument of Dr. Fitch. Indeed, a single example of syphilis following leprosy in the same individual destroys his theory.

H. S. Orme, M.D.

175 North Spring Street,
Los Angeles, Cal.

screwed down we may hope that the alcohol will boil at 79° or 80° ., and that not more than one-fifth its volume will evaporate in an hour's boiling. Such a result will usually follow, but we cannot depend upon its doing so. On the one hand, the leakage may be more than this; on the other, the jar may be so tightly sealed as to allow the alcohol to rise to 90° or 95° C., and the gut is rendered useless by an hour's exposure to this temperature. It is far better to boil the alcohol under ordinary atmospheric pressure and then recondense it. Thi gives a [illegible], of Buda-Pesth, ...es in the *Centralblatt für klinische Medicin* of October 22, 1892, concerning his experience with pilocarpine for the relief of singultus. He gives the hydrochlorate in doses of ten drops of a one per cent. solution three or four times a day in cases of nervous hiccough. The same effect, though in less marked degree, is obtained by atropine in large doses. Possibly quicker results might be obtained with pilocarpine used hypodermically, but the author does not seem to look with special favor upon this mode of application.

M. Villemin, whose death occurred in Paris on October 6th, was Vice-President of the Academy of Medicine of that city. He startled the Academy in 1865 by a communication in which he maintained that what we now recognize as the various manifestations of tuberculosis were but different forms of one and the same disease, modified according to the particular tissue involved. He also held that it was an infectious disease. The discussions to which this article gave rise lasted an entire year, and then the majority of the members of the Academy, while unwilling to condemn M. Villemin, yet refused to accept his views concerning the unity and the contagiousness of tuberculosis. He had the privilege, which is not accorded to every man, of living to witness his own triumph.

Swallowed a Tooth.—A writer in the *Deutsche Monatschrift für Zahnheilkunde* reports the case of a domestic who, while taking a drink of water, swallowed a false tooth which had been held in position by a metal plate. All efforts to extract the tooth failed, and the woman died of hemorrhage a few days later. At the autopsy it was found that the plate had caused a perforation of the œsophagus just above the entrance to the stomach.

Dr. Dabbs, Tennyson's physician during his last illness, is a dramatic writer as well as physician. He has written several plays, which are said to possess considerable merit, and has also written some very good poetry.

A New Street Danger.—The improvement in the paving of New York streets has given a great impetus to bicycling in this city, and has at the same time added to the dangers which pedestrians have to face in crossing the streets at night. People are knocked down by the silent wheel daily, and recently a noted lady violinist was thrown down and barely escaped a fracture of her arm. We have no wish to repress bicycling, but it should be regulated in some way and made less of a menace to life and limb.

Germ-free Water.—Drs. V. and A. Babes have made a number of experiments to determine the best method of purifying water for drinking purposes (*Centralblatt für Bacteriologie*, July 30, 1892). Filtration, they claim, is not only useless as far as removing the micro-organisms is concerned, but actually favors bacterial growth. Alum has been found by them the best, not only for clarifying water, but also for purifying it. Powdered alum is added to water, which is then well shaken and allowed to stand twenty-four hours in a cool place. At the end of this time the water is not only clear but quite free from germs. The addition of alum in large quantity is harmful since it leads to digestive disturbances. About ten grains to the gallon is amply sufficient to accomplish the desired end. After four or five days' use the vessel is emptied, washed out with sterilized water, and refilled. Water can also be rendered free from germs by the addition of sulphate of iron or of chalk-powder and sulphuric acid; in the latter case carbonic acid is given off.

Washing Out the Stomach.—Dr. Fenwick is not an enthusiastic admirer of indiscriminate lavage of the stomach. In an article in *The Practitioner* some time ago he showed that attacks of convulsions and tetany, as well as syncope and sudden death, have followed resort to this measure. There are also cases on record in which fatal poisoning has been caused by antiseptic materials used for washing the stomach.

"**Yujno-Russkaya Meditsinskaya Gazeta**" is the name of a new weekly medical journal published in Odessa, the first number of which is dated October 1, 1892. It is the official organ of the Odessa Medical Society. The "South-Russian Medical Gazette" is what the title means in English.

Bleeding from the Skin.—Dr. Deryabin reports the case of an apparently healthy girl, eighteen years of age, who suffered from profuse hemorrhage from the skin of the forearms, ends of the fingers, and tip of the nose. The hemorrhage lasted for about four hours, and the amount of blood lost was so great as to endanger life and to give rise to marked symptoms of acute anæmia. There was no cause appreciable for the attack, and the skin from which the bleeding occurred showed no lesions whatever, save that there was a patent orifice of a cutaneous gland visible at the tip of the nose.—*Vratch*, No. 31, 1892.

Gout in a Child.—Dr. Marboux reports in the *Lyon Médical*, for October, 23, 1892, a typical case of gout occurring in a girl, eleven years of age. The mother of the child was healthy, and the father had suffered only once from a slight attack of gout nine years before the child was born.

The Insanitary Condition of Rouen.—The Paris correspondent of *The Lancet* writes, anent the occurrence of cholera in Rouen, the following: "To sum up, at Rouen only one house out of five—3,000 out of 15,000 houses—has a supply of wholesome drinking-water; only one cesspool out of three cesspools has any pretence to be water-tight; more than 10,000 cesspools allow their foul liquid contents to escape in the sub-soil; out of 162 kilometres of streets only 42 kilometres of streets have sewers. Many of the streets are devoid of sunlight. The sewers—the surface drainage—poison the confined atmosphere. What wonder that the infant mortality is the highest in France, and that the general mortality reaches the alarming figure of 35.32 per 1,000 of the population. What wonder that typhoid fever is endemic, that diarrhœa has assumed an epidemical intensity, and that cholera has found in Rouen ready victims. May the mischief go no further, and may the warning be taken in time. Good water is available, good drainage is possible; both should be at once secured."

Vis Medicatrix Naturæ.—The *Hospital Gazette* has picked up the following legend somewhere, and publishes it without comment: "It is stated that a miser, named Elwes, when both his feet were equally injured by an accident, consulted a surgeon, who began to expatiate on the severe character of the wound and on the good fortune of his having been sent for. On this Mr. Elwes said, 'Now, Mr. Sawbones, I have one thing to say to you. I do not consider myself much hurt, whereas you think I am, so I will make this agreement; I will take one leg and you shall have the other; you shall do what you please with yours, and I will do nothing to mine, and I will wager you the amount of your bill that my leg gets well first.' Elwes delighted in telling this story, and used to assert with triumphant glee that he 'beat the apothecary by a fortnight.'"

A Restricted Diet.—A correspondent sends the following anecdote to the *Medical Press*: "Sir Richard ——, being called to a patient who fancied himself very

ill, told him ingenuously what he thought, and declined prescribing, thinking it unnecessary. 'Now, you are here,' said the patient, 'I shall be obliged to you, Sir Richard, if you will tell me how I must live—what I may eat, and what not.' 'My directions as to that point,' said Sir Richard, who abominated this sort of question, 'will be few and simple; you must not eat the poker, shovel, or tongs, for they are hard of digestion; nor the bellows, because they are windy; but anything else you please.'"

Typhoid Fever at Nice.—Continental authorities rejoice, says the *Medical Press*, in special and peculiar facilities for keeping secret the occurrence of local outbreaks of disease, and curiously enough the first intimation of its existence is often given in the columns of the English daily press. According to Dr. Allen Sturge, of Nice, the average death-rate from typhoid fever in that town during the summer quarter was below the average, or, at any rate, not above. He is, however, forced to admit that during the month of September the mortality from this source was rather more than double that of last year. The correspondent of an English journal calls attention to the prevalence of epidemic disease in that city at the present time, urging intending visitors to defer their departure until an official report has made it clear that a sojourn in this charming town is not attended with grave danger to health and life. The fact is that the sanitary law in France is wofully defective, and the authorities lack the power to enforce even the most elementary precautions in the event of an epidemic.

A Prize for the Invention of a Microphonic Audiphone.—Baron Leon de Lenval, of Nice, offers a prize of three thousand francs to the inventor of the best application of the principles of the microphone in the construction of a portable apparatus for the improvement of hearing in deaf patients. Instruments for competition should be sent to Professor Adam Politzer or Professor Victor V. Lang, Vienna, before December 31, 1892. The prize will be awarded at the Fifth International Otological Congress, to be held at Florence, in September, 1893. If no instrument is judged worthy of the prize, the jury reserve the right of announcing another competition, unless Baron de Lenval decides to otherwise dispose of the prize. The members of the jury are: Drs. Adam Politzer (President), and Victor V. Lang, of Vienna; Benni, of Warsaw; Gellé, of Paris; Urban Pritchard, of London; St. John Roosa, of New York; and Grazzi, of Florence.

A Crematorium at Glasgow.—A memorial has been presented to the Necropolis Committee in Glasgow from a cremation society asking for permission to build a crematorium, chapel for funeral services, and columbarium for the deposit of cinerary urns in the Necropolis. The memorial was referred to the Directors of the Merchants' House, and they have published it in their report, with the view of learning the state of public opinion concerning the proposal.

A Case of Lead-poisoning from a bullet embedded in the head of the tibia has been reported by Dr. Küstel. The symptoms subsided in a short time after the extraction of the missile.

Strychnine in Inebriety.—Dr. R. M. Phelps, of the Minnesota Hospital for the Insane, has made a series of investigations to determine the value of strychnine in inebriety, and formulates the following conclusions: 1. Nitrate of strychnia, taken steadily in large doses, has a tendency, first, to impair the appetite for liquor; later, to make liquor an incompatible or sickening agent for the time being. 2. The systematic effects of nitrate of strychnia seem to be not injurious. Yet I would be far from advising any private or injudicious use. 3. Chloride of gold and sodium was only given in small doses the last five days of the twenty-one, and it is only mentioned here because it seemed to bring out a positive sickening tendance on the patient, and see that the former underclothing and clothing are thoroughly disinfected by either sulphur, boiling in water, steam or spraying with disinfectant cologne, and allowed to dry, and shall not attend any non-contagious disease without a permit from the health officer. Every clergyman conducting burial service over the body of any person dying of either of said diseases shall observe the regulations given above for physicians."

Yellow Fever at Santos.—Reports [illegible] Santos, Brazil, M.D. Vol. II., Part I. 4to, 44 pages, illustrated.

Text-Book of Nervous Diseases—being a Compendium for the Use of Students and Practitioners of Medicine. By Charles L. Dana, A.M., M.D. With 210 illustrations. 8vo, 524 pages, red parchment muslin, price, $3.25. William Wood & Company, New York.

Diseases of the Chest, Throat, and Nasal Cavities, including Physical Diagnosis and Diseases of the Lungs, Heart, and Aorta, Laryngology and Diseases of the Pharynx, Larynx, Nose, Thyroid Gland, and Œsophagus. By. E. Fletcher Ingalls, A.M., M.D. Second edition, revised and enlarged. 240 illustrations. 8vo, 700 pages, extra muslin, price, $5.00. William Wood & Company, New York.

The Ready Reference Handbook of Diseases of the Skin. By G. T. Jackson, M.D. 8vo, 553 pages. Illustrated. Lea Brothers & Co., Philadelphia, Pa.

Medical Microscopy. By F. J. Withered, M.D. 8vo, 406 pages. Illustrated. P. Blakiston, Son & Co., Philadelphia, Pa.

Practice of Medicine. By Edwin T. Doubleday, M.D., and J. D. Nagel, M.D. 12mo, 221 pages. Lea Brothers & Co., Philadelphia, Pa. Price, $1.00.

Gynecology. By G. W. Bratenahl, M.D., and Sinclair Tousey, M.D. 12mo, 211 pages. Illustrated. Lea Brothers & Co., Philadelphia, Pa. Price, $1.00.

On Congenital Obliteration of the Bile-ducts. By John Thomson, M.D. 8vo, 52 pages. Illustrated. Oliver & Boyd, Edinburgh.

A Manual of Medical Jurisprudence and Toxicology. By H. C. Chapman, M.D. 8vo, 237 pages. Illustrated. W. B. Saunders, Philadelphia, Pa. Price, $1.25.

A Manual of Physics. By W. Peddie. 8vo, 501 pages. Illustrated. G. P. Putnam's Sons, New York. Price, $2.50.

The Mastoid Operation. By S. E. Allen, M.D. 8vo, 111 pages. Illustrated. Robert Clark & Co., Cincinnati, O.

Tuberculosis of Bones and Joints. By N. Senn, M.D. Royal octavo, 520 pages. Illustrated. Cloth, $4.00, net; sheep, $5.00; half-Russia, $5.00, net. The F. A. Davis Co., publishers, 1231 Filbert Street, Philadelphia, Pa.

A Manual of Medical Jurisprudence. By Alfred Swain Taylor, M.D., F.R.S., revised and edited by Thomas Stevenson, M.D., London. Eleventh American edited with citations and additions from the twelfth English edition, by Clark Bell, Esq. Royal octavo, 787 pages. Illustrated. Price, cloth, $4.50; sheep, $5.50. Lea Brothers & Co., Philadelphia.

Fever Nursing. By Mary Harris. 12mo, 67 pages. The Record Press, London.

Diseases of Children. By C. A. Rhodes, M.D. 12mo, 170 pages. Lea Brothers & Co., Philadelphia. Price, $1.00.

screwed down we may hope that the alcohol will boil at 79° or 80° ., and that not more than one-fifth its volume will evaporate in an hour's boiling. Such a result will usually follow, but we cannot depend upon its doing so. On the one hand, the leakage may be more than this; on the other, the jar may be so tightly sealed as to allow the alcohol to rise to 90° or 95° C., and the gut is rendered useless by an hour's exposure to this temperature. It is far better to boil the alcohol under ordinary atmospheric pressure and then recondense it. This gives a constant temperature and very little liability to mishap. Hence very small-sized gut may be used, with the knowledge that it will be strong after the preparation.

I submit the accompanying apparatus as the simplest I have yet seen.

A condenser (Fig. 1) is made by encasing a coil of block tin tubing in a cylinder of sheet copper. The height of the cylinder is 7 inches; its diameter, 3½ inches. The length of the tubing is 4 feet; its internal diameter, ⅛ inch. A piece of the tubing, 5 inches in length, projects from the top of the cylinder, and is shaped into a hook. A straight piece, 2 inches in length, projects from the bottom. The condenser may be suspended by this upper hook, or may rest on a retort-stand or tripod. Two taps are inserted into the cylinder for the transmission of water in and out. The lower one is attached by rubber tubing to a faucet for running water, the upper one is fitted with a rubber tube to provide for the escape of the water. The catgut is put into alcohol in such a jar or bottle as is convenient. The piece of block tin tubing at the bottom of the condenser is fitted into a perforation in the cork of this bottle or jar.

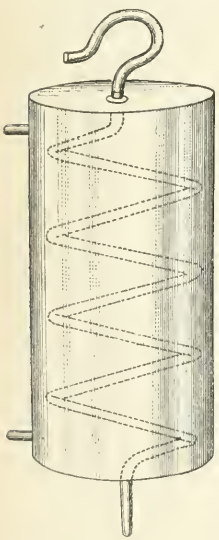

Fig. 1.

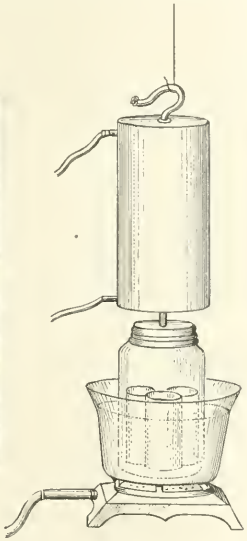

Fig. 2.

A water bath is made by placing a small basin of water on a gas stove or over a Bunsen burner.

The apparatus should be so placed that the jar which contains the alcohol is partly immersed in the water (Fig. 2). Heat is then applied to the water-bath until the alcohol boils. It may be kept boiling as long as is desired without especial attention, and with no loss of alcohol, since it is recondensed as fast as it is vaporized, and drops back into the bottle. The capacity of the condenser is such that the vapor from a quart of alcohol is condensed as rapidly as it is produced by ordinary boiling. The alcohol after an hour's boiling and recondensing shows no trace of either tin or lead from the tubing. A bit of absorbent cotton should be inserted in the upper end of the tubing.

The apparatus may be obtained from the W. F. Ford Surgical Instrument Co., Thirty-second Street and Fifth Avenue, New York City.

This method puts within the reach of every surgeon an easy and efficient way of obtaining catgut which is aseptic, and which is pliable and strong. It is believed that boiling alcohol is much more efficient than any chemical antiseptic solution, which weakens the catgut so little.

Oil or fat is a great protection against the action of chemical solutions. Silk threads [2] which are impregnated with pus bacteria and then dipped in oil, may lie for days, and even for weeks, in an aqueous 1 to 2,000 solution of corrosive sublimate without the killing of the bacteria. Catgut is regularly greasy before it has been bleached, and in the process of twisting it much of the greasy surface is turned into the interior of the strand. It is thus particularly difficult to destroy the life of the bacteria or spores, which are carried within the strand in the twisting, and are there more or less protected by fatty matter. Boiling alcohol is a very strong solvent of fatty matter, and is thus especially well fitted to penetrate the small crevices in the catgut, and so to bring the germicidal action of the heat and the alcohol to bear on all contained bacteria and spores.

Heated liquids seem to have remarkable germicidal power. Boiling water [2] kills spores in two minutes which withstand steam ten to fifteen minutes, and dry heat at 140° C. two to three hours. Heider [3] found that five per cent. carbolic acid solution, when heated to 75° C., killed anthrax spores in three minutes, although they were not killed in it at the room temperature in thirty six days.

The germicidal power of boiling alcohol is certainly greater than that of the chemical solutions ordinarily used in the preparation of catgut. Hodenpyl [1] found that anthrax spores were regularly killed by it within forty-five minutes. Let us see what the action of sublimate and carbolic acid solution is upon these organisms. Geppert [4] saturated threads with anthrax spores, and immersed them in 1 to 1,000 aqueous corrosive sublimate solution for varying lengths of time. On removing them he precipitated the adherent sublimate with ammonium sulphide, and then placed the threads in culture-media. He found that after one, two, and three hours in the sublimate solution a few spores retained their power of growth, and in one exceptional case he obtained a growth beside a knot in the thread after twenty-four hours' immersion. Behring [5] obtained growths from anthrax spores which had been immersed in 1 to 1,000 sublimate solution for ten hours. Nissen [6] found that anthrax spores could live after a four hours' immersion in one per cent. corrosive sublimate solution. They have repeatedly retained their power of growth after being immersed for days in a five per cent. carbolic acid solution.[3, 7, 4, 11]. Thus we see that boiling alcohol is a much more powerful germicide than the solutions of carbolic acid or corrosive sublimate which are ordinarily used.

Although anthrax spores are considered the most resistant of infective agents,[8] it is important that the medium which is used for sterilizing the catgut should be capable of killing them, since there is always a possibility that they may exist in the sheep's intestine, from which the so-called catgut is prepared. Volkmann [9] has reported two cases where anthrax pustules appeared in wounds at the points where catgut sutures were taken. He thought the infection due to the catgut.

This efficacy of boiling alcohol is no more than we would expect from other observations than those of Hodenpyl. The following table shows a few of the results which have been obtained by studying the germicidal effect of various media at different temperatures :

Germicidal agent.	Temperature at which it was used.	Kind of micro-organism.	Length of exposure necessary for killing the micro organisms.*	Observer.
Boiling water.	100° C.	Anthrax spores.	2 minutes.	Geppert, Berl. klin. Woch., 1890; p. 246; Schimmelbusch, Arch. f. klin. Chir., xlii.
Boiling water.	100° C.	Bacilli and cocci.	2 to 5 seconds.	Ibid.
Boiling water.	100° C.	Staphylococcus pyogenes aureus; bacillus pyocyaneus.	2 to 3 seconds.	Ibid.
Boiling one per cent. aqueous solution of sodium carbonate.	100° C.	Anthrax spores.	2 minutes.	Ibid.
Boiling one per cent. aqueous solution of sodium carbonate.	100° C.	Pus; staphylococci; bacillus pyocyaneus.	2 to 3 seconds.	Ibid.
One and four-tenths aqueous solution of sodium carbonate.	85° C.	Anthrax spores.	8 to 10 minutes.	Behring, Zeitsch. f. Hygiene, 1890, p. 451.
One and four-tenths aqueous solution of sodium carbonate.	80° to 83° C.	Anthrax spores.	10 minutes.	Ibid.

* The times given are not absolute, because in all cases the organisms were exposed to a certain varying heat while the medium was being heated and was cooling.

Three facts are very well illustrated by this table: 1. There is great advantage in using heat in disinfection. 2. Liquids heated to a temperature of 60° to 80° C. kill all known infective agents, in some cases in a few seconds, in others in a few minutes. 3. The micro-organisms which ordinarily cause suppuration are far easier to kill than the anthrax spores which are used as tests.

Judging from the results expressed in the table, we would expect that the ordinary pyogenic bacteria would be killed in boiling alcohol in five minutes or less, and anthrax spores in about half an hour. This corresponds well with Hodenpyl's results. Hodenpyl used ninety-seven per cent. alcohol with a boiling-point of 79° C. I have found that the boiling-point of the ninety-five per cent. alcohol obtained from a reliable druggist is about half a degree higher. The more water there is in the alcohol the higher is the boiling-point, the greater the germicidal power when boiling, and the greater the injury done to the catgut by the process.

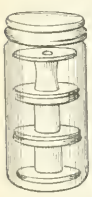

Fig. 3.

Another advantage in this method comes from the ease with which infection of the catgut may be prevented after it is once sterilized. Professor Halsted [10] has devised an excellent method of sterilizing his silk ligatures and sutures on bobbins in test-tubes, and using them one by one as needed. A somewhat similar device may be used for catgut. Glass reels are made, each half an inch long, with flanges one inch in diameter which are so shaped that the ends of the reels are concave. Two or three yards of gut can be wound on each without overlapping enough to prevent the free access of the alcohol. Three of them fit, one above the other, in a small cylindrical screw-topped jar † (Fig. 3). Rubber washers are fitted into the covers of these jars, and they, containing reels of catgut, filled with alcohol, and having the caps screwed on, are put, three at a time, in a pint Mason preserve-jar. The pint jar is then three-fourths filled with alcohol, attached to the condenser, and put in the water-bath. After an hour's boiling the small jars are taken out and their caps tightened. Each reel may be taken from the jar as it is needed. The surgeon holds it in his left hand and unrolls the gut as he ties the ligatures. It unrolls easily if the reel is held loosely between the thumb and third finger so that the nails are in contact with its concave ends. The flange protects the gut from contact with any foreign substance until it is unwound. Thus from the time the gut is sterilized until it is applied in the wound, the only foreign substance which it touches is the hand of the surgeon. It is not exposed to infection from contact with perforated stoppers, necks of bottles, scissors, forceps, towels, gowns, hands of assistants, etc. That which remains in the jar has not been disturbed. It is not difficult to tie the ligatures with the reel in the hand, if the hands are crossed in tightening either the first or the second half of the knot.

† Whitall, Tatum & Co's one-ounce Glycerine Jelly-Jars.

I made a series of experiments in attempting to seal the jars tightly after they contained the gut and the alcohol, and then putting them in a steam sterilizer. In this way I hoped to subject the gut to the action of alcohol, at a temperature of 100° C., and so to sterilize it more quickly and easily. I tried all the available varieties of preserve-jars and fitted rubber disks and washers into several kinds of small screw-top and clamp-top jars. None of them retained the vapor of the alcohol under pressure without leaking. The pressure was sufficient to bulge the metal cap of four-ounce screw cap jars, and to force out rubber washers which were clamped down with strong screw clamps, and to force up a rubber stopper so that the heavy twine which held it pressed into it one-quarter inch.

A jar can doubtless be constructed which will stand this pressure, but there would always be the danger of a slight leak which would escape detection, but which would prevent the alcohol from rising much above 80° C. Alcohol under pressure at 90° to 100° C. weakens catgut in a short time. Hence, in attempting the method, we are dealing with very uncertain elements. If there is a little leakage the gut will not be sterilized by a short exposure in the sterilizer; if there is no leakage it will be

made useless by a long exposure. Boiling at atmospheric pressure with a fixed temperature seems still the best and most reliable method.

THE INFLUENCE OF DIATHESIS UPON THE PROGRESS OF PHTHISIS.[1]

BY S. E. SOLLY, M.D.,

COLORADO SPRINGS, COL.

AT the meeting of the Climatological Association, held in Washington, September, 1891, Dr. Alfred Loomis read a paper founded on the post-mortem examinations of 524 patients dying in Bellevue Hospital, of whom eight per cent. presented evidence of arrested pulmonary tuberculosis. In all cases fibrosis had taken place around the tuberculosis tissue, confirming, as he writes, the statement of Ziegler that "the arrest of tuberculosis can only take place when the inflammatory process issues in the development of fibrous tissue."

Dr. Loomis goes on to state that a condition of intense hyperæmia always surrounded the tuberculous areas when recent fibroid processes were active, leading him to believe that this was an essential condition. He then asks the question, Why do these reparative processes occur only in a limited number of tubercular subjects? and says the answer is found in the diathetic tendencies of different individuals, and writes as follows: "In one person the tendency to fibroid development is above the normal of systematic harmony. In another rapid parenchymatous cellular developments occur under purely physiological stimulus, and become excessive under pathological. We call these conditions fibroid and strumous diatheses. It is, however, important to remember that fibroid processes which are injurious under some conditions may become directly conservative under others, and two opposing diatheses may result in the relief or cure of diseases produced by one or the other, the result being obtained by the very intensity of the diathetic condition. Whenever necrotic changes occur in the parenchymatous tissue, fibroid development is the only method of repair; but when the cause of the necrosis is especially powerful only a pathologically strong fibroid activity will suffice for its arrest. The histories of many cases of pulmonary tuberculosis afford striking proof of this antagonist action of diathesis. I have long been convinced that there is a relative immunity possessed by arthritic individuals, not only against pulmonary, but against all forms of tuberculosis, and I have made many observations which appear to me to prove that in a patient whose parents suffered from general fibrosis, or who presents active evidence of this diathesis, tuberculosis of the lungs, bones, joints, and glands shows a marked tendency to assume a chronic course and to a spontaneous cure." He next proceeds to give the brief outlines of some typical cases.

With the view of pursuing this inquiry, so ably opened by Dr. Loomis, I have analyzed the 141 cases of phthisis previously reported by me, and whose temperamental peculiarities and their influence on the progress of the disease I presented to you at our last annual meeting. Of the 141 cases 25 had gouty tendencies, that is, 10.6 per cent., the percentage of improvement among those without this diathesis was 65.8, and those with it 66.6, showing only one per cent. greater improvement among the gouty cases.

[1] Read before the Colorado State Medical Society, June 22, 1892.

Of the 141 cases 58 per cent. showed a family predisposition toward phthisis; the percentage of improvement among these was 69, while among the non-hereditary cases it was 61.4 per cent.

Among the gouty, however, the per cent. of improvement in those with hereditary phthisis is reversed, being higher in the non-hereditary, the combination of both inheritances being the worst, the percentage of improvement among the hereditary with gout being only 33.3, while among the non-hereditary with gout the percentage was 66.6, about up to the average.

With Respect to the Duration of the Disease.—Previous to coming to Colorado the gouty cases averaged a year longer, and in the total duration of the illness, that is before and after coming, the difference is still more marked, the gouty cases lasting a third longer, that is, nine years instead of six, so that the gouty cases were slower both in improvement and deterioration.

The known syphilitics in the series were only two, and one improved and the other did not. This, of course, gives no sufficient data, and I have not so far investigated this matter. My impression is, however, that the gross results in cases of combined syphilis and tuberculosis would be found very similar to what has been found in connection with gout.

Six of the 141 cases were rheumatic, of whom 5 improved, being the high percentage of 84.3, while the total duration of those cases was only three years and ten months.

GOUT.

Before coming to Colorado:

	Years.	Months.
24 Gouty cases	3	8
117 Non-gouty cases	2	4
Total Duration of Illness:		
Gouty cases	9	0
Non-gouty cases	6	4
Rheumatic cases	3	10

Improved:

	Per cent.
Gouty cases	66.6
Non-gouty cases	65.8
58 Hereditary cases of phthisis	69
83 Non-hereditary cases of phthisis	61.4
3 Hereditary with gout	33.3
21 Non-hereditary with gout	66.6
6 Rheumatic	83.3

Although, as I have elsewhere demonstrated by comparison with the reported cases of other physicians, the 141 cases from which these observations are taken may be considered as fairly representative, yet they are, of course, too few to safely generalize upon; therefore these figures can only be correctly judged when many more are taken to compare them with. So far, however, they do not bear out the opinion of Dr. Loomis, that the gouty diathesis is necessary to procure arrest in most cases of phthisis, as we find the percentage of improvement in the gouty and non-gouty nearly the same. And, on the other hand, when we look into the cases of hereditary phthisis, where we would expect to find the opposing or strumous diathesis generally developed, we find the percentage of recoveries eight per cent. higher, and this is confirmed by the cases of Dr. Fisk and others, the former's being 73 per cent. This, while admitting that arrest must come through local fibrosis, appears to negative the assumption that a diathetic tendency to fibrosis, as is exhibited in gout, is an aid to recovery. The greater percentage of improvement among those in whom inheritance was marked is probably due to the evident fact that such persons are on the look out for becoming phthisical, and place themselves earlier under treatment than those whose family are free from taint, and when affected are more cautious in their conduct.

Among the six rheumatic cases we find an unusually high percentage of improvement, about fifteen per cent.

higher than the general average. But these cases are too few to form any conclusions from.

Of the twenty-four cases of gout only three had also an hereditary tendency to phthisis, which would aid in confirming Dr. Loomis's opinion of the opposition between the two diatheses.

When we come to the belief expressed by the Doctor that the fibroid diathesis tends to increase the duration of phthisis, we find strong evidence in its favor, the gouty cases being a third longer in duration than the non-gouty. And I feel sure that the complete record of the entire number of cases of phthisis I have had under my care would fully confirm this. On the other hand I have formed the opinion that where the manifestations of gout are active in the individual, and accompanied, as they usually are, with hepatic and gastro-intestinal derangements, the hindrance to nutrition, comfort, and exercise that these usually cause more than counterbalances the possible advantages of a more energetic local fibrosis. Further, I am inclined to believe that it is among such that we find most cases where deterioration and death appear to ensue from too expensive and unchecked fibrosis, after the tuberculosis process has been apparently arrested.

It seems to me, however, very probable that a slight inherited tendency toward gout which does not proceed to any seriously disturbing symptoms affords the best chance of the tuberculosis being checked by an early, sufficient, but not overmastering fibrosis.

There is, however, a possibility that my observations made upon phthisis treated at an altitude yield different conclusions to those made on cases treated in low climates, for the reason possibly that the effect of lessened barometric pressure, in conjunction with the other attributes of an elevated climate, may cause a much greater tendency to fibrosis; and so, on the one hand, more often oppose successfully the strumous diathesis, and, on the other, aggravate the gouty or fibrous diathesis, so as not only to first cure the disease, but later kill the patient with the remedy. The statement of Dr. Loomis that local hyperæmia appears an essential condition in fibrosis would help to explain the working of this suggested influence of altitude in procuring fibrosis, as it is generally believed, for good reasons, that high climates induce pulmonary hyperæmia. Moreover, as it would appear probable the healthy lung is expanded by the demand for increased oxygen, and so compresses the diseased portions, we have another reason for fibrosis being specially induced.

The present time may seem an unfortunate one for discussing the influence of gout, when the very existence and diagnosis of this ancient and revered enemy of the human race is being called in question. But although time and space do not permit us here to weigh the evidence upon this subject, all who have had much clinical experience must admit the fact of a condition of ill health which we recognize and call by the name of gout, account for it and explain its phenomena how we may.

The Sitting Posture During Delivery.—Dr. J. T. Webster, in the *Medical Brief*, gives the following reasons for preferring the sitting or squatting position to the dorsal decubitus during labor: 1. Because the law of gravitation naturally assists in the expulsion of the fœtus. 2. Because the leaning of the body forward, and pressing of the abdominal muscles against the thighs, assist materially the expulsion during contractions of womb. 3. It relieves the colon, lumbar nerves, and perineum of the weight of the child. 4. It avoids the continual getting up to evacuate bowels or empty the bladder. 5. It prevents the laceration of the perineum by relieving it of the downward pressure against it. He especially observed that as soon as cases assumed this position they were satisfied, and were greatly relieved of all the unnecessary pain and discomfort of labor.

Progress of Medical Science.

Glycerine in the Treatment of Hepatic Colic.—Dr. Ferrand has published a paper on this subject with the following conclusions: 1. Glycerine administered by the stomach is absorbed as such by the lymphatic vessels, notably by those which proceed from the stomach to the hilus of the liver and to the gall-bladder; it is found even in the blood of the subhepatic veins. 2. It is a powerful cholagogue and a valuable remedy in hepatic colic. 3. In large doses (5 to 8 drachms) glycerine cuts short the paroxysm at once. 4. In smaller doses (1 to 4 drachms) glycerine, taken daily in a little alkaline water, prevents the return of the attacks. 5. Glycerine, although not a lithontriptic, is the remedy *par excellence* for biliary lithiasis.—*La France Médicale.*

The Moral Side.—In an address before the Marion-Sims College, Dr. C. H. Hughes says: "The study of the physician includes the moral as well as the physical well-being of man, for the purity of the soul has much to do with the health of the body. The purity of the heart and the dominance of the body by principles of rectitude, has much to do with the health and consequent happiness of present and succeeding generations. The direct and hereditarily entailed diseases which are the offspring of sin, and *vice versa*, which have filled and are filling the land with misery and woe, both physician and divine are alike especially interested in preventing. The psychology of sin and the pathology of crime are studies alike for doctor and divine. The man who is sick in his soul is seldom well in his body, and the soul's affairs do not prosper well when the body is disordered. Like the divine, the physician may also aid in healing 'the wounded in spirit and the broken-hearted,' and in 'binding up their wounds.' He may 'minister to a mind diseased,' and 'with sweet oblivion's antidote cleanse the stuffed bosom of that perilous stuff which weighs upon the heart.' He does this effectually through the modern successful management of melancholia."—*Alienist and Neurologist.*

Menstruation and Lactation.—It is a generally received view that the supervention of menstruation during the period of lactation is prejudicial to the quality of the maternal milk-supply, and therefore detrimental to the nutrition of the child. Most practitioners will probably state as a matter of observation, that menstruation unfits the mother as a nurse by reducing the quantity of the milk, in addition to rendering it more "watery." In order to ascertain the real effect of menstruation on the quality of the milk, Dr. Schlicter has made a series of analyses which seem to show that the current belief is founded on defective observation. In addition to careful examination of the composition of the milk during and after menstruation, he had the child weighed and its general condition noted at and after the same period. He reports that in respect both of casein and fat, the milk secreted during menstruation compared favorably with that furnished prior to that date. The differences observed, moreover, in no case equalled those which occur in the milk of the normal healthy female at the various periods of the same day; hence he declines to attach any importance to them.—*Dietetic Gazette*

The Dyspnœa of Advanced Bright's Disease.—Dr. Steell thinks that common dyspnœa of advanced stages of Bright's disease is due to heart failure, and is not toxæmic. He points to the benefit obtained in many such cases from the hypodermic injection of morphia, as inconsistent with the presence of toxæmia. He recommends digitalis, or when it fails, strophanthus, citrate of caffeine, nux vomica, or strychnia. In paroxysmal dyspnœa he says the nitrates are disappointing; he recommends morphia, enjoining caution in its use, and its combination with atropine.—*The Birmingham Medical Review.*

New York, December 3, 1892.

THE PRACTICAL SIDE.

THE season is approaching when the doctor must look to the business side of his profession, make up his annual, semi-annual, or quarterly accounts, and send out his bills. And a pity and a shame it is that so many of those bills will never be heard from again. We hear a good deal of the evil of dispensaries and free hospitals, and of the injury they work to the young physician in depriving him of the practice that is justly his due, and the evil is truly great. But it sinks into insignificance in comparison with far greater and more widespread evil of the delinquent patient. The dispensary abuse works injury to the young physician chiefly, and to those living in or near large cities, but the crime of the dead-beat affects all alike, the young and the old, the urban and the rural practitioner. It is not too much to say that, overcrowded as the physician is, there are few who would fail to support themselves and their families, in an humble way at least, if they could but collect all that is due them for services rendered.

But physicians themselves are not entirely blameless in the matter. If they were better business men and were more honest to themselves they would be less frequently defrauded of their pay. In the first place, they are often careless in keeping up their books, letting them go unposted sometimes for weeks, and then when they do attempt to write them up, many items are forgotten and the dates of the visits made are omitted or guessed at. The books are thus rendered valueless as evidence, and the physician is liable to be non-suited if in his desperation he attempts to collect his bills by process of law. The only safe and the only business-like way for the man in busy practice, or in practice at all, is to write up his books every day, putting down the number and dates of the visits and office consultations and the amount charged for the same This takes a little time, but it is time well spent, and will save time and money too in the end.

Another fault of the physician is in the matter of charges. The relations of the family physician to his patients are often of the most intimate and confidential character. He is frequently the confidant of his patients and is entrusted with family secrets and accounts of all the financial and other troubles which afflict them. He learns perhaps that business has been bad, or the crops have been poor, and it will be hard work to pay the interest on the mortgage, and he naturally sympathizes with the people in their trouble, and concludes to make no charge against them for his services. But the holder of the mortgage does not take off any of the interest due him, the storekeeper does not furnish them with goods for nothing, or even at cost price, the wheelwright doesn't mend their farm wagons gratis. Neither does the storekeeper or the blacksmith or the wheelwright work for the doctor for nothing. If the horse casts a shoe he must be shod, if the buggy or sleigh breaks down it must be repaired, or the doctor will be unable to visit these patients (whom he is too kind-hearted to charge) when they send for him in the night. But the new shoe for the horse, the new wheel on the buggy, the new shafts in the sleigh must be paid for.

Keep your books properly posted, have a fixed rate of charges, send out your bills promptly at regular intervals and insist upon their being paid promptly—in other words, have business methods in transacting the business part of your profession. Then you will be more likely to live in moderate comfort while you are here, and to leave a provision for your family when you are called away.

SURGICAL WORK AT MACUTO, VENEZUELA.

REPORTS from La Guayra, Venezuela, give vivid accounts of surgical aid rendered wounded Venezuelan soldiers of both parties, by the naval medical officers of the flagship Chicago. Medical Inspector J. Rufus Tryon, U.S.N., Fleet Surgeon of the North Atlantic Station, acting under orders of Rear-Admiral Walker, proceeded at once to Macuto as soon as it was known that there were a number of wounded in that vicinity suffering for want of surgical attention. Dr. Tryon had associated with him in the interests of humanity, Passed Assistant-Surgeon Urie and Assistant-Surgeon Whitfield of the Chicago; Staff-Surgeon Triggs of the British navy; Dr. Paramitto of the Spanish navy, and Staff-Surgeon Thalen of the German navy. Their duties were most arduous, and according to the reports in detail made to the Admiral by Medical Inspector Tryon, and just received at the Navy Department, continued during several engagements, and until the final success of General Crespo as Provisional President of Venezuela.

Dr. Tryon was directed to take to Macuto such medical and surgical supplies as he deemed necessary, from the Medical Department of the Chicago, and was most fortunate in having at hand all that could be required to establish a modern hospital, successfully equipped for the treatment of every case coming under the classification of military surgery.

The good results following all the surgical work that was done, can only be owing to the skill of Dr. Tryon and his assistants, and the abundance of necessary supplies at his command.

We can only now mention some of the principal grave surgical operations that were performed, and results, referring our readers for details to the special reports of Medical Inspector Tryon that will soon be published with the Annual Report of Surgeon-General J. Mills Browne, U.S.N.

Death followed in only two cases after surgical operation for severe gun-shot wounds, viz., one amputation at shoulder-joint, parts partially gangrenous at time of op-

eration, and the case of excision of hip-joint, where the ball was found to be embedded in the sacrum.

The following are the operations: One excision of the hip-joint, two amputations at shoulder-joint, one amputation at superior part of upper third of thigh, one amputation at lower third of thigh, one amputation at lower third of leg, one excision of the shoulder-joint and resection of arm, one excision of first metatarsal and partial resection of second metatarsal, one operation at upper part of hip, for removal of bones in compound comminuted fracture of the ilium.

Dr. Tryon and his associates are to be congratulated for their military service at Macuto, as it was conscientiously performed in the cause of humanity regardless of the dangers attending it. The Geneva Cross was unknown and unheeded by the soldiers in Venezuela.

Before the flag-ship Chicago left La Guayra, General Guerra, second in command of the Venezuelan forces, accompanied by his staff, made an official visit of inspection of the hospital organized by Dr. Tryon at Macuto, and conveyed the thanks of General Crespo and the Venezuelan Government for the services rendered their wounded by the medical officers of the American navy.

FREE TRADE AND THE MEDICAL PROFESSION.

Some of our contemporaries are urging the immediate removal of the tariff on microscopes, medical and surgical implements and scientific works. In scaling down the tariff, we believe that the medical profession should be on the alert to see that its interests are provided for. We want our surgical instruments as cheaply as possible, and we have quite the same right to a reduction as any other profession, or class of workers. At the same time it is a convenience to have prosperous surgical instrument makers at our doors; and we do not want to have to send to Germany every time we need a new kind of knife, or a new surgical implement of any kind. Therefore, it is better that the medical profession will not urge free trade in surgical instruments at once. The same is true of books and microscopes. There are several prosperous firms making these latter instruments, and they also have interests at stake. Let the profession urge its rights to cheaper products, but keep in mind what is due to those supplying us now.

HELP FOR THE PAN-AMERICAN CONGRESS.

When the International Medical Congress was held in Washington, five years ago, the National Government, if we recollect correctly, appropriated a modest sum to aid in entertaining the visitors and sustaining the work of the Congress. This courtesy has been extended by nearly all the governments and municipalities in the countries where the meetings have been held.

It is establishing no precedent, therefore, when the representatives of the Pan-American Medical Congress ask for some aid. This Congress could be made of much more practical, public value to the United States in many ways, than could an International Congress. For it will bring together men best versed in the sanitary conditions of the Southern Republics; men also of liberal education, whose knowledge of, and sympathy with, our institutions would lead to closer fraternal feelings, as well as indirectly to commercial benefits. The better Pan-Americans know each other, the better it will be for this Western hemisphere, and the proposed Congress will form a factor of great public importance as well as of technical interest.

Again, Washington, as a city, is unable to extend the municipal hospitalities on the scale demanded by great meetings, and Congress has in a great measure assumed municipal functions in the District of Columbia. Hence, as representing the city, it ought to deal generously by its American guests. There is no subsidy in this, any more than when any city government helps along great meetings and demonstrations for the public good.

We note that some of our medical societies have passed resolutions praying Congress to make an appropriation to defray some of the expenses of the All-American meeting. Such action should be imitated all over the country. But in addition, the societies should see to it that their Congressmen are directly appealed to. The passing of resolutions by a county medical society will of itself have about as much effect on the average Congressman as one rhubarb pill on a very constipated elephant.

News of the Week.

State Association of Railway Surgeons.—At the second annual meeting of the New York State Association of Railway Surgeons, held at the Academy of Medicine, November 14th, Dr. George Chaffee, of Brooklyn, was re-elected President.

Dartmouth Medical College held its ninety-fifth Annual Commencement on November 22d, and conferred diplomas upon a class of twenty-eight.

Collapse of a "Gold Cure."—An institution established at Long Branch, for the cure of inebriety on the injection plan, has gone to pieces, owing to lack of money and patients.

The City of Hamburg last week celebrated its relief from the epidemic of cholera. There are still a few new cases daily reported in the city, but the epidemic has ceased and the mortality-rate is at its normal average.

Dr. Franklin H. Hooper, of Boston, one of the most eminent laryngologists of New England, died on November 23d, from cancer of the throat. Dr. Hooper was forty-two years old. At the time of his death he was attached to the Massachusetts General Hospital, and was Professor of Laryngology at Dartmouth Medical College.

A Sterile State.—According to the last census one-fifth of the married women of Massachusetts are childless. Suffolk County seems to be a particularly barren spot, 23.89 per cent., or nearly one-fourth, of the married women being childless. We should like to know if this is due to arsenical wall-paper, or to growing Democracy, or to just plain culture combined with sterpiculture.

Surgeon-General of Connecticut.—Dr. Patrick Cassidy, of Norwich, has been appointed by Governor-elect Morris Surgeon-General of Connecticut.

Typhoid in St. Louis.—There is a serious epidemic of typhoid fever in St. Louis; nearly thirteen hundred new cases have been reported during the past week.

The American Public Health Association meets this week at the City of Mexico.

New York Polyclinic.—Dr. W. H. Katzenbach has been elected Professor of General Medicine at the New York Polyclinic; Dr. Andrew J. McCosh, a Professor of Surgery; Dr. Florian Krug, a Professor of Gynecology; and Dr. Edward B. Dench, a Professor of Otology.

Railway Surgery at the Pan-American Medical Congress.—A Section of Railway Surgery of the Pan-American Medical Congress has been organized, with Dr. C. W. P. Brock, of Richmond, Va., as Executive President. A full list of officers has been provided for each of the constituent countries.

They Don't Do It.—The *Medical Progress* is informed that the regular profession in Louisville consults with homœopathic physicians freely and whenever an opportunity presents itself "for a fee." *Progress* denies this, and says: "The homœopathic members of the faculty of Louisville amount to but little. It is rare that one hears of a homœopath, and we cannot help believing that our contemporary has been grossly misinformed."

Pylorectomy and Vivisection.—Experiments on animals for the purpose of studying the best methods of intestinal suture have been cited as illustrations of the value of vivisection. Replying to this, Mr. Lawson Tait makes the following extraordinary statements: "Resection of the intestine does not differ in any one of the principles involved, nor very much in details. In whatever part of the intestinal canal it is practised 'pylorectomy' has nothing therefore to single it out as a case where experiments on animals are required more than in other parts of the intestine. But if Mr. Jessett wishes to claim for it such a character I will grant his premise at once, because it is one of the class of operations which I utterly condemn. I have never done it, and I never shall, for the disease is malignant nine hundred and ninety-nine times in a thousand, and inevitably returns. In the odd case where the disease is not malignant the operation of pyloric dilatation (Loreta) has been shown to be sufficient. We now know also that such operations as gastro-enterostomy lead to permanent and continuous fecal regurgitation, so that the whole scheme of such operations is gradually being dropped. This is the fate I predicted for them years ago." Surely nothing could be more absolutely false than this. Without going into statistics it is sufficient to say here, that in New York, within a short time, two operations for gastro-enterostomy have been successfully done, with great, and so far permanent, relief to the patients.

Some Legislation that Georgia Needs.—The *Atlanta Medical and Surgical Journal* says: "The Georgia Legislature last year passed with a rush a bill prohibiting physicians from getting drunk, but strangled in committee meeting another requiring the medical colleges of the State to adopt the three-year course, thereby assuming the Pharisaic attitude of tithing mint and anise and cummin, while neglecting the weightier matters of the law. There is one matter which the Legislature of Georgia ought to consider. In fact it can no longer afford not to do so. This State needs, and needs badly, a Board of Medical Examiners, who shall pass upon the fitness or unfitness of those wishing to practise medicine within its limits." A committee has been appointed by the Atlanta Society of Medicine to prepare and submit a bill to the General Assembly providing for the establishment of a State Board of Examiners.

The Cooper Medical College of San Francisco has adopted a four years' course.

Sir Andrew Clark and Doctors in Politics.—Sir Andrew Clark's sixty-sixth birthday took place a few days ago, on which occasion the editor of the *Evening News and Post* wrote: "Sir Andrew Clark will be known to all future ages as the physician of Mr. Gladstone. A native of 'dear old Scotland,' he is in some ways the best-hated man in the profession. He is a physician and a teetotaller. Many people say of him and his class, 'A physician may be the greatest quack in the world. A surgeon you can test; he operates successfully or not; but the doctor, who sees what no one else sees, and hears what no one else hears, and knows what none others know, can't be tested.' Sir Andrew Clark, however, can be tested by this one proof of success, that he has kept alive and energetic our Premier to the age of eighty-three. Sir Andrew is said to be indignant at the nonsense talked at the dinner given to Sir Walter Foster, the first medical man who has ever been in office in England. The reason why medical men don't get into political office, of course, is clear; the medical man can't get promoted to a judgeship, or county court judgeship, or magistrate's office by getting into the House. The barrister can. Wisely then he sticks to the mortar and pestle. Of the ten doctors now in Parliament, all, save Sir Walter Foster, are Irish or Scotch Home Rulers."—*Hospital Gazette.*

The Dangers of Honest Journalism.—The question whether honest, outspoken journalism pays so well as namby-pambyism, and the oblique puffing of quackery, is one which sometimes forces itself on one's notice. A few months since we dared to call in question the behavior of the treasurer of a certain London institution—which shall be nameless for the present—in his public capacity, and forthwith both the subscriptions and the advertisements to this journal were at once stopped, at the direct instigation of the hyperæsthetic official. A little later we thought it our duty to call attention to the so-called "Chloride of Gold Cure for Inebriety," and before very long we were served with a notice of action for libel. This week we have to acknowledge the receipt of another of these interesting missives. Count Mattei is aggrieved at our remarks on cancer-curing, and failing to extract a humble apology for venturing to question his wonderful powers, he, too, has caused a writ to be served upon us for "damages, for injunction, and for costs;" the latter goes without saying where lawyers are concerned.—*Medical Press.*

Scientific Obstetrics as Conducted at Winkel's Clinic at Munich.—In the obstetrical department the annual average of births is about eleven thousand, of which the great

majority are illegitimate, this latter being due to the fact that criminal abortion in this country is very rare, the laws being very strictly enforced, and the offender severely punished. The sale of drugs that may produce abortion is forbidden, and they are only to be had on the prescription of a legal practitioner. The work in the obstetrical department is conducted as follows: As soon as the parturient or pregnant woman comes in, she is examined by the physician on duty to see whether labor has actually begun; if not, she is either sent home, or, if confinement is expected within a short time, taken in to be occupied in the clinic, and also in the courses given to students in the methods for examination of the pregnant, and in acquiring manual dexterity. If she is found to be in labor, she is ordered to undress, the skin is examined for scabies; if found this is treated at once, and her clothes, before return at the time of discharge, properly disinfected. Pediculosis pubes, if found, is also treated at once, the parts being shaved. She then receives a bath under supervision of the midwife on duty, and is given a bed in the confinement chamber. Her history is taken, then her general health is inquired into, the lungs, heart, etc., examined, then abdominal examination follows and all conditions are carefully noted. I may here state that external examination, palpation, auscultation, and pelvimetry ought to be much more generally impressed on the student's mind by teachers of obstetrics than it has in the past. With comparatively little practice it is astonishing what dexterity one may acquire in diagnosing the exact position of the child, thus reducing internal examination to a minimum, not only to the mother's comfort, but also lessening the danger of sepsis through the accoucheur's fingers.

I have learned to value the pelvimeter; it often enables one to foretell a prolonged case of labor when least expected by the general aspect of the patient. This holds good, especially in flat rachitic pelves of a slight degree, when the history of the case gives no information. By taking accurate measurements of the pelvis we can diagnose slight contractions early in labor, and can inform the relatives of probable operative interference. This will only tend to strengthen the confidence of the patient in the physician, when, if the life of child or mother is endangered, the obstetrician states the necessity of such interference. This will often obviate the embarrassing situation when relatives, confronted with facts, hesitate, and will not consent to an operation being performed until valuable time has been spent in calling consultation, thus losing a living child.

The examination of the parturient is concluded by the internal examination, after thorough disinfection of the hands and forearms of the operator, and the vulva and adjoining parts of the mother. Intravaginal disinfection was abandoned long ago, and is now only practised in cases of gonorrhœal infection. The method of disinfecting the hands in this hospital is as follows: The nails, which are kept short and smooth, are cleaned dry at first. Hands and forearms are brushed in hot water with soap for three minutes, changing the water several times; this procedure is followed by brushing for two minutes in a solution of bichloride of mercury, 1 to 1,000. The brush used is a large hand brush, not such as you find on a lady's toilet stand. Sublimate causes in some, at first, an eczema, but it generally passes away in a day or two, never to reappear. After disinfection of the hands *nothing* is touched—water faucets, bedclothes, or anything else. The midwife in attendance lifts the blankets; the physician with two fingers of one hand separates the labiæ, and introduces one or two fingers, not oiled, but direct out of the bichloride solution, of his other hand in the vagina, then the mother is covered again.—*Cor. Occidental Medical Times.*

Laying of the Corner-stone of the New York Post-Graduate Medical School and Hospital.—The corner-stone of the large new building which the New York Post-Graduate Medical School and Hospital is about to build at the northeast corner of Second Avenue and Twentieth street, was recently laid. The Rev. Marvin R. Vincent, of Union Theological Seminary, opened the exercises with prayer. Dr. D. B. St. John Roosa, President of the corporation, made a brief address and laid the corner-stone.

The address of the day was delivered by Dr. T. Gaillard Thomas. He described the origin of the school in 1882, and sketched its course since. It began with less than one hundred students, and now numbers over five hundred. Its sole object, he said, was not only the instruction of physicians who wish an enlarged knowledge, but also the creation of similar centres of learning in other cities of the country. In the course of his remarks he said: "The time has surely arrived when a Secretary of Public Health, chosen from the ranks of medicine, should constitute one of the members of the cabinet of the President of the United States; when quarantine, with the host of questions which cluster around that word, should be a national, and not a State, function; and when medical men should be so thoroughly informed upon hygiene, by competent instructors in all our colleges, that no political body in our land would dare to stultify itself and insult public opinion by placing a merchant at the head of the Health Board of one of the largest seaports in the world."

The new medical school and hospital is to be a five-story building of Indiana limestone and white brick. It will front one hundred and ten feet on Twentieth Street and ninety feet on Second Avenue. It has not been modelled after any other medical school or hospital in the city. To the eye it will look like a handsome business building. The idea was to construct a building in which the students, being practitioners of medicine, could meet their instructors at the bedsides of patients. It will contain two clinical lecture-rooms, with ante-rooms for the preparation of patients and their examination in detail by one or more practitioners, an operating amphitheatre, and numerous small rooms for special study. It will accommodate one hundred and eighty patients and one thousand students.

A Medical Pavilion of Roosevelt Hospital.—Mrs. Abram A. Anderson has offered $350,000 to the Roosevelt Hospital for the founding of a medical pavilion in memory of her father and mother. The only conditions of the gift are that the clinic shall be free to students, and be under the charge of Dr. Francis P. Kinnicutt. The trustees promptly accepted the gift with thanks.

Reviews and Notices of Books.

Essentials of Medical Diagnosis. By S. Solis-Cohen, M.D., Professor of Clinical Medicine in the Philadelphia Polyclinic, etc., and Augustus A. Eshner, Instructor in Clinical Medicine in Jefferson Medical College, etc. Pp. 382. Philadelphia: A. B. Saunders. 1892.

This manual is No. 17 of Saunders's Question Compends Series, which we have already commended in these columns. The present addition fully sustains the reputation of its predecessors. Meant for students, it is properly written from their standpoint and confines itself well to its text. It is a very good book for the student to begin with, as it will guide him in the perusal of the larger treatises on medicine. As implied in the title, diagnosis is the point aimed at, and no reference whatever is made to treatment.

Transactions of the Medical Association of Georgia. Forty-third annual session, 1892. Pp. 320. Published by the Association at Atlanta, Ga. 1892.

In addition to the usual official reports the volume contains twenty-three papers of interest. The general appearance of the Transactions is most creditable.

Fourteenth Annual Report of the State Board of Health of the State of Connecticut, for the Year Ending November 30, 1891. Edited by Charles A. Lindsley, M.D., Secretary State Board. Pp. 649. New Haven: Tuttle, Morehouse & Taylor. 1892.

The contents cover a wide range of topics, including not only matters of public hygiene, sewerage, water supply, etc., but also elaborate tables of vital statistics. Several valuable reports of bacteriological analysis of drinking-water are included. Too much praise cannot be awarded to Dr. Lindsley for the able manner in which the volume has been compiled. It well serves as a model for all similar publications. Much of the technical work of examination of water, etc., has been done by the chemical department of the Yale University Medical School, under the able supervision of Prof. Herbert E. Smith, Dean of the Medical Faculty.

Colotomy: Inguinal, Lumbar, or Transverse, for Cancer or Stricture with Ulceration of the Large Intestine. By Herbert W. Allingham, F.R.C.S., Surgeon to Great Northern Hospital, etc. 8vo. Pp. 198. London: Baillière, Tindall & Cox. 1892.

The book is a collection of the author's experiences in the various operations of colotomy, and an attempt to arrange and explain, in a systematic manner, the principles which guide him in his practice. It is, therefore, largely written from a clinical standpoint. It consists of a large number of clinical histories with full details of operative technique, illustrated by fairly well executed woodcuts. The type is broad and attractive in appearance.

The author's well-earned reputation will secure many readers among those who follow the surgical craft. While the impress of his own originality is everywhere shown, he gives a kind and cordial recognition to the work of others.

Surgical Treatment of Neuralgia of the Fifth Nerve. By William Rose, M.B., F.R.C.S., Professor of Surgery, King's College, etc. Pp. 85. London: Baillière, Tindall & Cox. 1892.

The three lectures constituting this volume were delivered on the Lettsomian Foundation before the London Medical Society, in 1892, and have already been published in *The Lancet* and *British Medical Journal*. Nevertheless, collected by themselves in separate form, they can be more carefully read, and with greater profit. Several woodcuts illustrate the operative procedures advised, and frequent references are made to the literature of the subject.

The Student's Handbook of Surgical Operations. By Frederick Treves, F.R.C.S., Surgeon to London Hospital, etc. Pp. 495. Philadelphia: Lea Brothers & Co. 1892.

This is an abridgment from the author's larger Manual of Operative Surgery, and therefore is concerned only with the most essential and most commonly performed operations. It is assumed that the student is familiar with general surgical anatomy, and with the principles of after-treatment.

Probably no writer on surgical topics is better able to condense more information into few words than is Mr. Treves. His own experience gives weight to what he says, and he is careful to separate the essential from the irrelevant. The book is one to be unhesitatingly commended.

A Treatise on Hygiene and Public Health. By Thomas Stevenson, M.D., Lecturer on Chemistry at Guy's Hospital, and Shirley F. Murphy, Medical Officer of Health of London, etc. Vol. I. 4to. Pp. 1013. Philadelphia: P. Blakiston & Co. 1892.

Seventeen contributors have labored to produce this monumental work. The topics treated are air, warming, and ventilation, meteorology, water, food, clothing, public hygiene in its several departments, influence of soil and climate on health, etc.; valuable references are made also to the inspection of food-products. Nine valuable plates are included in the volume.

All the topics are treated with a thoroughness of detail leaving nothing to be desired. The contents are valuable alike to the physician, the municipal health officer, and the sanitary engineer.

Proceedings of the United States Naval Institute. Vol. XVIII., No. 3, 1892. Annapolis, Md.

The present volume consists of six lectures on First Aid to the Injured, and on Transportation of the Wounded, by Henry G. Beyer, M.D., Ph.D., M.R.C.S. The lectures are copiously and well illustrated, and form altogether one of the best and most complete brochures upon these subjects that we have seen.

Gladstone on the Medical Profession.—According to the *Pall Mall Gazette*, the Grand Old Man has a very high opinion of physicians. It seems that some German writer made the statement that Mr. Gladstone had prophesied that doctors were destined to become the leaders of the people. Somebody who saw the quotation wrote to the veteran statesman for confirmation or contradiction. Mr. Gladstone wrote in reply: "So far as regards the exact words cited in your letter I cannot positively say aye or no, and I rather think that I should in using them have added some qualifying or limiting expressions. But it is certainly a fact that for a very long time I have believed the medical profession to be both in a state of absolute advance from the progress of its science—this it may be said is a mere commonplace—and of relative advance from the particular features attaching to our civilization in its onward movement."

Beri-Beri in New York.—Five Chinese sailors on the British steamer Tetartor, which arrived from the Philippine Islands recently with a cargo of raw sugar, were found to be suffering with beri-beri. The vessel was seventy-five days making the voyage, and when it had been one month at sea, a Chinese sailor died of the disease. The Health Department was notified and an inspector had the five sailors removed to the Hospital for Contagious Diseases at Flatbush.

Society Reports.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 9, 1892.

H. P. Loomis, M.D., President, in the Chair.

Difficult Diagnosis.—Dr. J. Lewis Smith presented specimens from a case in which the diagnosis was doubtful. The patient, Agnes M——, three years of age, was admitted to the New York Foundling Asylum three months ago, in an apparently dying condition. No history of her condition immediately preceding her admission could be obtained. At the time of entering the asylum the radial pulse was imperceptible, the respirations were 64, and the temperature 106° F. in the rectum. Soon after this she was seized with severe general convulsions, for which no cause could be assigned. The urine was examined, but with negative result. The child improved rapidly after these convulsions ceased, and was soon apparently well. She remained in this condition for three months, when suddenly, at 3 A.M. on November 4th, she had another attack of convulsions, accompanied by a rise of temperature to 105° F., and the pulse 180, with 58 respirations per minute. Seven hours later she was partially conscious, the convulsions had been controlled, and auscultation of the chest showed only harsh respiratory sounds. The urine still continued to yield a negative result on examination. She passed a fairly quiet night, and when first seen by the speaker on the following morning, her pulse was 140 F., respirations 44, and temperature 104° in the rectum, and she had a peculiar vacant stare. When the arms were raised above the head, and percussion made in the axillary region on the right side, some dulness was found, but only harsh breathing was heard over this area. There were no other symptoms present, and after a careful examination the only diagnosis which was made was that of pneumonia of the upper part of the right lung. Shortly afterward the urine was again examined, and was found to contain about twenty per cent. of albumin, and some hyaline casts. By evening the pulse had reached 150, and was quite feeble, necessitating the employment of stimulants. The respirations were 43, and the temperature 105° F. The following morning the temperature was 104°, and the child was constantly rolling the head and throwing herself about the bed. She died at 6 P.M.

At the autopsy the upper and posterior portions of the brain were found to be congested, there was some œdema over the convexity. On cutting into the brain, the sinuses were found filled with long fibrinous plugs, and in some portions these were blood-stained. The larynx and trachea were normal. The upper lobe of the right lung was uniformly consolidated, the finer bronchial tubes, posteriorly, contained dark red and slightly granular plugs of fibrin. A similar exudate was found over the portion of pleura corresponding to this part of the lung. The heart, liver, and spleen were normal. The intestines contained a good deal of mucus, and the solitary follicles and Peyer's patches were swollen, but not ulcerated. The kidneys were swollen and congested, the capsules not adherent, and the markings were obscure.

Even in the light of the pathological examination, the diagnosis was still doubtful. There was a possibility of the case being one of cerebro-spinal meningitis. Ever since 1871, when the disease first appeared as an epidemic among the horses of car lines, it had been endemic in this city, although at present cases of this kind were comparatively rare. It would seem, however, that in this case there had been sufficient time for the formation of an exudation of fibrin around or upon the brain at some point, and there should have been during life some rigidity of the spine and retraction of the head. Shortly before death, this child was able to bring the head forward to take a drink. It was possible, also, that the child might have had a mild form of typhoid fever, which had been overlooked until the occurrence of the severe symptoms which ushered in the pleuro-pneumonia. In young children it is sometimes extremely mild, and runs its course in from five to nine days. He had seen typhoid fever occur in children who were up and around during the whole course of the disease, yet the diagnosis was confirmed by the adult members of the same family soon developing the disease in its typical form. Personally, he was of the opinion that the severe convulsions in the case just reported accounted for the condition of the brain, but he could not explain the appearances found in the intestinal canal.

Malignant Ulcerative Endocarditis.—Dr. Eugene Hodenpyl presented two specimens of above. The first specimen was removed from David C——, forty one years of age, a laborer of intemperate habits, who had had eight attacks of acute articular rheumatism, and for ten years past had suffered from palpitation and dyspnœa on exertion. For the past four months the dyspnœa and palpitation had become much more troublesome, and had been associated with cough and muco-purulent expectoration. The urine had been scanty during the last two months, and the patient had rapidly emaciated. One week before admission his feet became swollen, and the dyspnœa quite severe, and when he entered the hospital his pulse was 102, respirations 28, and the temperature 100.2° F. The urine had a specific gravity of 1.010, and contained a trace of albumin. The apex of the heart was found in the fifth space, in the nipple line, and its action was regular. There was a loud systolic murmur, and a circumscribed presystolic murmur at the apex. One week after his admission he suddenly lost consciousness, and died in a few hours. During his stay in the hospital his temperature had been irregular, varying from 99° to 101° F. The autopsy showed a sacculated pleurisy, with effusion in the lower part of the left chest, and both lungs œdematous and partially consolidated. The heart-muscle was flabby, the aortic valves thickened, and the mitral valve was thickened, stenosed, and covered with vegetations. It was also the seat of ulceration, and immediately behind this was a small abscess. The right heart was normal. The kidneys were small, and contained many cysts; the capsules were adherent, and the cortex thinned, and the markings obliterated. The blood-vessels at the base of the brain appeared to be normal. The left hemisphere was occupied by a very large blood clot. Dr. Cheesman made cultures from the ulcerated mitral valve, and these showed the presence of the streptococcus pyogenes.

The second specimen was removed from Alfred W——, forty-seven years of age, a man of intemperate habits. He stated that he had had chancre twenty-two years ago, but had never had rheumatism. One week before admission, after exposure to wet, he began to cough and to expectorate dark colored mucus, and three days later he was seized with severe pain in the right side of the chest, the breathing became more rapid, and, according to his friends, he was occasionally delirious. On admission, he was slightly cyanosed, the pulse was 118, respirations 48, and the temperature 102.8° F. The urine had a specific gravity of 1.04, and contained a trace of albumin, and granular and hyaline casts. Physical examination showed dulness from the right apex anteriorly to the fourth rib, and from the fourth to the sixth rib tympanitic resonance with bronchial breathing over the area of dulness, and bronchovesicular respiration over the tympanitic area. All over the right side of the chest, anteriorly and posteriorly, were numerous crepitant râles, and posteriorly there was dulness down to the angle of the scapula, and below this tympanitic resonance. Over both areas breathing and voice were bronchial in character. Over the left side of the chest, posteriorly from the apex to the angle of the scapula, and near the vertebral column, bronchial râles were heard, but these are evidently transmitted from the right side. All over this side of the chest the breathing and voice were exaggerated. The apex-beat of the heart

was imperceptible, and the heart-sounds were heard most distinctly in the fifth space The action of the heart was regular but feeble. The patient remained almost constantly delirious, with an irregular temperature, varying from 102° to 104 5° F., until his death, nine days after admission. The autopsy showed recent adhesions over the upper part of the right lung, and a few old adhesions over the posterior part of the left lung; the latter was congested and œdematous. Portions of the right lung were consolidated, and the whole lung was studded with large and small abscesses, some of which communicated with branches of the pulmonary artery. The heart was flabby, and there were patches of thickening on the visceral pericardium. The aorta was normal, but the aortic valves were greatly thickened and stenosed, and were the seat of extensive ulceration, which had produced perforation through one cusp. The papillary muscle was streaked with pus. There was also hypertrophy of the wall of the left ventricle, with dilatation. The spleen was enlarged, soft, and friable. The left kidney was large and pale, its cortex was thick, and the markings indistinct, while the right kidney was the seat of several red and white infarctions. Cultures made by Dr. T. M. Prudden from the heart vegetations, papillary muscle, kidneys, and lungs, showed the presence of the streptococcus pyogenes; and cultures from the abscesses in the lungs showed the presence of the staphylococcus pyogenes aureus. Those made from the spleen were negative.

Dr. T. M. Prudden said that the bacteriological literature of malignant endocarditis was so meagre, that every opportunity should be improved for making cultures, and enlarging our knowledge of this subject. Apart from its intrinsic interest, it was a perpetual source of instruction, for it illustrated the importance of a local lesion in favoring the growth of the bacteria. It is probable that in every case of malignant endocarditis there is some antecedent lesion of the valves which has caused the development of the growth of bacteria in this situation. It is a little curious that the bacteria circulating in the blood should not set up a suppurative inflammation in the glandular organs, but when once beginning on the valves of the heart, secondary abscesses are very prone to follow.

Miliary Tuberculosis and Gummata, Occurring in the same Lung; Their Differential Diagnosis.—Dr. Hodenpyl also presented a specimen showing miliary tubercles and gummata in the same lung, and exhibited the characteristics of each under the microscope. The specimens were removed from a middle-aged man, who died in the hospital of delirium tremens. Notwithstanding his habits of life, he was an example of unusually good physical development, and all the organs except the right lung were normal. This lung showed in its upper two-thirds a considerable number of small, grayish, hard nodules, closely resembling in appearance the miliary tubercles. Scattered about the lung were other and larger nodules, about one-fourth of an inch in diameter, round and hard. On section they presented a white surface, and surrounding them was a zone of pearly hue. It was interesting to note in connection with this case, that although this man was intemperate and dissipated, and had considerable disease of the right lung, there were no symptoms during life referable to this condition, and the tubercles and gummata were shown under the microscope to be fibrous. The case was a rare one, and of unusual interest, as bringing up the question of the differential diagnosis between tubercles and gummata. Although there is apparently no good reason why they should not be associated together, especially as we know that syphilis is very apt to be followed by tuberculosis, this was the first time he had met with the two conditions in the same organ. It is well known that chancre and chancroid cannot be differentiated by microscopical examination, and that the morphological characteristics of tubercular and syphilitic inflammation have many points in common. In many cases the specific bacterium of tuberculosis may be of assistance in the diagnosis, but as yet there are no well founded claims for the existence of such an organism in cases of syphilis. The following points of differential diagnosis may be emphasized, although, of course, there are many exceptions to the general statements made:

1. The history of tuberculosis in the one case, and of syphilis in the other, may be of importance.

2. The bacteriological examination is usually positive in tuberculosis, unless the tubercles are very old and fibrous; it is negative in syphilis.

3. Inoculation experiments are usually positive in tubercle, and negative in gumma.

4. Tubercles are usually present in considerable numbers, and are scattered throughout the entire organ, and throughout the body; gummatous deposits are usually single, or are present in small numbers, and are confined to a single organ.

5. Tubercles are usually much smaller than gummata.

6. Tubercles show a marked tendency to undergo cheesy degeneration and to form cavities; gummata rarely become cheesy, usually drying up and undergoing calcification.

7. Amyloid degeneration is sometimes present in tubercles, but, so far as known, is absent in gummata. On section, the tubercles appear as round or irregular grayish masses, often soft or cheesy in the centre, and surrounded by a zone of inflammatory products.

8. Microscopical examination will show the presence of tubercle bacilli in the tubercles; but no characteristic micro-organism is present in syphilis. Giant cells are present usually in tubercles, and are usually absent in gummata.

Dr. J. S. Ely exhibited under the microscope specimens of gummata from a case of hereditary syphilis in a child. In its structure the specimen very closely resembled that of miliary tubercles.

Dr. Martha Wollstein also exhibited a slide illustrative of the difficulty of differentiating between syphilis and tubercle. The specimen was taken from the lung of a child twenty-two months old. There was no family history of syphilis. The maternal grandfather died of acute phthisis about one year before the birth of the child. At the time of admission to the hospital, there was dactylitis, a consolidation of the right lower lobe of the lung, and a very fetid purulent otitis. At the autopsy the left lung and pleura appeared to be normal. The right lung also appeared normal, except the lower lobe. This was covered by recent pleuritic exudation, and the substance of the lobe was riddled with cavities of varying size, filled with a soft cheesy material. The parietal pleura over this lobe was studded with small masses, apparently cheesy, and similar masses were found on the peritoneal surface of the diaphragm. There were also a few small, solid nodules in the lower lobe of this lung, which resembled gummata, and even on microscopical examination the existence of giant cells and also of cheesy matter made the differential diagnosis extremely difficult. The peritoneum also showed the presence of cheesy matter and of giant cells. The liver, spleen, and kidneys were absolutely normal. About fifty sections were stained, but no tubercle bacilli were found; hence, the diagnosis of syphilis was made.

Melano-sarcoma with Melanuria.—Dr. J. S. Thacher presented specimens from two cases of above. Both occurred in St. Luke's Hospital, one in the service of Dr. Davis, and the other in that of Dr. Ball. In the first case there was an enormous melanotic tumor of the liver, probably secondary to a similar growth in the eye. In the second case there was a large melanotic growth at the base of the left lung, also several subperitoneal tumors, and two similar growths in the posterior part of the left cerebral hemisphere. In one case the correct diagnosis was suspected shortly before death, and in the other a partial diagnosis was correctly suggested. Both cases gave a marked reaction for melanine in the urine, and they are reported chiefly on account of the assistance which this urinary reaction sometimes renders in making

the diagnosis, particularly where, as in these cases, the other symptoms were obscure.

The first patient, the one with the tumor of the liver, was a sea captain, forty-nine years of age, who, for two years previous to his death, had experienced great distress after eating, a sense of constriction about the waist, and sometimes a sharp stabbing pain. He sometimes vomited, with relief, but he had never raised any blood. For the past year he had noticed an enlargement of the abdomen, and during this time he had been troubled with constipation and flatulence. During the last few months of his life he lost flesh and strength rapidly. There was slight jaundice at times. On examination, the liver was found to nearly fill the abdomen, and sixteen ounces of a dark-brown fluid were withdrawn from the abdominal cavity by aspiration. At the autopsy the liver was found reaching to within two inches of the symphysis pubis, and to within one inch of the extreme left of the abdominal cavity, the top of the diaphragm lying on the right side at the level of the third rib, and on the left side at the level of the fourth intercostal space. The liver weighed twenty-nine pounds, or as much as eight or nine normal livers. Its right lobe was very firm, of a dark-bluish color, and presented on its surface numerous whitish nodules, one to six millimetres in diameter. On section, it was of a dark-brown color, with nodules like those found on the surface. The left lobe presented a cystic tumor, ten inches in diameter, and on puncturing it dark blood spurted out. On introducing the finger into the cavity, the contents appeared to be soft clots No other tumors were found. Some years ago the patient had had one eye enucleated for some trouble, the nature of which could not be ascertained. The heart, spleen, and kidneys presented on section an unusually dark color.

The second patient was a housewife, fifty-three years of age, who had been under observation only five days before her death, and whose mental dulness prevented her giving a satisfactory history. She suffered from general malaise, vomiting, often brought on by eating, and headache. Her pulse was rapid and feeble, but regular. The temperature was normal, except that on the day of her death it rose to 101.6° F. The physical examination of the chest showed only dulness on percussion over the lower part of the left lung, and at the upper border of this area of dulness the respiratory murmur was increased, and there were subcrepitant râles. She stopped breathing and became cyanotic when turned on her right side, one quarter of an hour before her death, but the breathing recommenced when she was turned again on her back. The usual examination of the urine was negative. At the autopsy there was found at the base of the left lung, and attached to the diaphragm, a nodular tumor six inches in diameter, black, partly of grumous consistency, and partly firm enough to slice. A similar nodule, two inches in diameter, was found at the surface of the left occipital lobe of the brain, and dipping into its tissue, and in the white substance of the posterior part of the left parietal lobe was a nodule, one and one-half inch in diameter. Four subperitoneal tumors presenting the same appearance, and varying from one and a half inch to two and a half inches in diameter, were found attached to the intestine, omentum, and abdominal wall. On section the heart, liver, and kidneys were of a dark color. Specimens were shown from the lung, peritoneum, and brain. Microscopical examination showed in both cases that the growths were spindle-cell sarcomata, with a large amount of pigment. The urine from the first patient was turned a very dark color on the addition of acids; hydrochloric acid colored the whole urine quite dark, and gave a very heavy black precipitate. The urine obtained from the bladder of the second patient gave the same reaction, though not so marked. Either nitric acid, or hydrochloric acid, produces a nearly black color, and a similar reaction is obtained on the addition of chloride of iron.

Dr. Thacher said other cases had been reported, in which the black coloring matter had been recognized in the urine, where internal melanotic tumors were present, yet the chemistry of this coloring matter is not well understood. When the urine is first voided, it is normal in color, but after standing a while it becomes darker, and the color is deepened by the addition of oxidizing agents. It has been stated that the coloring matter was not always of the same composition, and that it has been detected in cases other than melanotic tumors—for instance, in marasmus; yet these are so exceptional, that the presence of the coloring matter may be considered of considerable value in diagnosticating the existence of melanotic tumors. The best reaction is obtained with a moderately strong solution of chloride of iron, the dark color first produced deepening after standing for some time. Dr. Thacher then demonstrated this test.

Miliary Tuberculosis of the Lungs and Kidneys, with Tubercular Ulceration of the Bladder.—Dr. D. H. McAlpin presented for Dr. Biggs two specimens: The bladder showed perforating ulcers going down to, and in some cases even through, the mucous coat. There were a few miliary tubercles in the lungs, and calcified areas at the apices.

Dr. Thomas H. Manley asked whether the point of original infection was in the lungs, or by way of the bladder, as it had been claimed that the kidneys might be affected by an ascending or a descending infection.

Dr. McAlpin replied that the tubercles of the lungs presented the ordinary tubercular cicatrices with calcification of the pleura. He could not say positively as to the origin of the infection, but it probably began in the lungs.

Dr. S. Alexander said that, at the present time, genito-urinary surgeons generally considered tubercular ulceration of the bladder to be much more common as a result of general tuberculosis than of secondary tuberculosis of the lungs. Personally, he knew that in many instances there is a tubercular ulceration of the bladder without any involvement of the lungs, though he had never seen tubercular ulceration or miliary tubercles of the bladder where the seminal vesicles or the prostatic urethra were not affected. He did not know whether or not the disease originated in an ascending infection of the urethra, but the comparative rarity of tubercular disease in the anterior urethra was opposed to such a view.

The Society then went into executive session.

How to Go to Bed.—We have still something to learn in the matter of nursing, according to Dr. Richardson, who tells us in *The Asclepiad* that in hospital, as in private practice, great errors are made in the choice of bedclothing for the sick, and particularly for the sick who are suffering from febrile affections. We have got rid of the heavy curtains around the bed; of the grand accumulator of dust and other uncleanness, the tester; of the heavy vallance, which converted the under part of the bed into a close cupboard, in which all kinds of unwholesome and cumbrous articles lay concealed, including sometimes excreted matter itself; and we have banished the carpet, which often, as a hard-trodden, dust-laden rag, made the floor beneath the bed persistently impure. This is all good; but the old feather-beds, flock-mattresses, heavy blankets, thick, impermeable, and dense counterpanes still encumber many a patient, rendering ventilation of his body as impossible as in the days of our forefathers. The art of going to bed is one which has been studied (and practised) for untold centuries. We have not advanced much on the practice of our forefathers in the West. According to Mr. Ernest Hart, and now according to Dr. Richardson, we "go to bed" in a very unwholesome and stupid fashion.—*British Medical Journal.*

Congress of Dermatology.—The next International Dermatological Congress will be held in London, in 1895, under the presidency of Mr. Hutchinson. The Congress of 1892 was held in Vienna.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

GYNECOLOGISTS TO THE FRONT—WHAT MAKES FOR SUCCESS IN ABDOMINAL SURGERY?—MR. LAWSON TAIT ON TRAUMATIC PERITONITIS — MR. BLAND SUTTON ON TUBAL MOLES AND TUBAL ABORTIONS—THE ADVANTAGES OF AMPUTATION THROUGH THE THIGH IN HIP-JOINT DISEASE.

LONDON, November 1, 1892.

GYNECOLOGICAL specialists have been very much in evidence of late, for discussions on subjects comprised within their specialty have recently taken place at three of the metropolitan medical societies. At the British Gynecological Society Mr. Hawkins-Ambler, of Liverpool, read a paper entitled "What Makes for Success in Abdominal Surgery?" He defined success as the regular, everyday success of the best operators, and not the isolated surgical triumph. He did not regard antiseptics as necessary, and thought the craze for them was a phantasy which was fast passing away; soap and water were more important. He insisted on the importance of absolute cleanliness in the practice of abdominal surgery, and criticised severely the action of surgeons who were careless about fouling the peritoneum with ovarian fluid, urine, fæces, or even pus. A small abdominal incision, when possible, was desirable. The great essential to uniformity of success was rapidity of operating, though nothing was to be shirked or hurried. It must be a factor in the case whether the peritoneum were exposed for ten or fifty minutes. Dr. Max Walthard's experiments showed that drying of the peritoneum was one of the chief causes of peritonitis. This was most surely obviated by rapid work, by promptitude in dealing with emergencies, and resource on the surgeon's part; it was to be mitigated by irrigating with saline solutions, or hot water flushing, at the close of the operation. As regarded drainage, it was difficult to make up one's mind. It might be the best rule to drain when in doubt, and once commenced, one should not be in too great a hurry to withdraw the tube. We should drain where hemorrhage was present at the end of an operation, where it was feared, where there were many adhesions, and where the peritoneum was fouled. We need not drain after flushing if the pelvis has been well dried and cleaned. With regard to after treatment, it was better not to catheterize, or give douches, or morphia, unless from some serious necessity. Many great operators were said to care nothing for temperature, something for pulse, and much for distention—a symptom which usually gave way to a dose of salts or of calomel.

Dr. Inglis Parsons spoke in favor of antiseptics. Some surgeons appeared to be able to dispense with them, but it must be remembered that the general hygienic condition of hospitals was vastly superior now to what it was formerly. Dr. Heywood Smith agreed that rapidity of operation was a matter of great importance, and that it was unwise to waste time in looking for the point of separation of the recti muscles. The catheter should only be used in case of absolute necessity. When the patient's tongue was dry and "typhoid" in character he gave from six to ten grains of dry calomel. He preferred silkworm gut sutures to silk sutures. Mr. Batchelor, of New Zealand, said he thought more lives were sacrificed from trying to operate through too small an incision than from any other cause, and since he had visited this country he had learned the advantage of making an incision large enough to permit of easy manipulation. The danger of exposure during the operation was exaggerated; in a properly conducted ovariotomy there should be no exposure of a kind to do harm. In cases of abdominal distention he had derived the greatest advantage from the insertion of a rectal tube with gentle massage of the abdomen; flatus was passed and the patient at once relieved. Mr. Reeves admitted that rapidity of operation was an advantage, but deprecated any pandering to the gallery; the surgeon's safest maxim was *festina lente*. The President said that once the patient had passed flatus after these operations he regarded her as safe, and this passage of flatus was, in his opinion, of greater significance than temperature or pulse. He had changed his views during the last few years in regard to the feeding of patients; formerly he only used to give slops for some days after the operation.

At a recent meeting of the Harveian Society Mr. Lawson Tait read a paper on "Peritonitis," limiting his remarks to peritonitis following operation. Mr. Tait remarked that he had come to discard all theories of inflammation, including the germ theory. There were, he said, no symptoms and no post mortem appearances whereby peritonitis which was septic could be distinguished from that which was not. The symptoms of peritonitis were numerous, but there was not one upon which absolute reliance could be placed. There were two symptoms which he always regarded with anxiety, viz., alteration of the patient's face and distention of the intestine. He had never seen fatal peritonitis in which distention was not a prominent feature. He considered that the cause of death in peritonitis was the disturbance of the ebb and flow of the serum stream of the peritoneum, and the disturbance of the function of the liver. Preventive treatment was best, for there was no chance of curing peritonitis. He gave up using opium years ago, on the ground that it masked the patient's condition and diminished the vermicular action of the bowels. He had discontinued the administration of ice for the treatment of thirst consequent upon opening the abdomen, and gave warm water in preference. Of late years he had diminished the amount of fluid to the vanishing point, and now absolutely starved his patients for nearly forty-eight hours after operation. If sickness occurred on the third or fourth day, all food (including water) was stopped for twelve hours. Should the patient be unable to pass flatus for twenty-four hours after operation the nurse proceeded, on her own responsibility, to administer a turpentine enema; if this did not succeed a mild purgative was given. He had never said that the purgative treatment would cure peritonitis.

Mr. Alban Doran said he agreed with Mr. Tait as to the advisability of keeping the patient's stomach empty for some time after operation. Nutrient enemata should, however, be given except in young or very robust patients, else in trying to prevent peritonitis the surgeon might kill the patient by starvation. Mr. Jackson Clarke protested against Mr. Tait's pathological opinions, and said the value of his paper was diminished from his not attempting to make any clinical distinction between traumatic and suppurative peritonitis. Mr. Malcolm observed that Mr. Tait had certainly formerly used words which might be taken to imply that peritonitis could be cured by purgatives. He disagreed with Mr. Tait's view as to the nature of peritonitis. He urged that it was an obstruction or a paralysis of the bowels that caused the distention and other symptoms, and that any peritonitis found after death was secondary to this complication. Dr. Heywood Smith said that the profession owed a debt of gratitude to Mr. Tait for having done so much to promote the administration of purgatives in the preliminary stage of peritonitis. When distention passed into peritonitis he quite agreed with Mr. Tait's recommendation of calomel. He gave it himself in even larger doses—eight or ten grains—and found it acted like a charm; it did not generally purge. Dr. Boxall described his experience at the General Lying-in Hospital in regard to scarlatina, and said it was strictly analogous to that of Mr. Tait in operation cases. He could not regard Mr. Tait's contention as to the worthlessness of antiseptics as in any way borne out by his own experience, in so far, at any rate, as he had founded it upon the spread of scarlatina.

At the last meeting of the Medical Society of London, Mr. Bland Sutton read a paper on "Tubal Moles and Tubal Abortion." Mr. Sutton said that in 1890 he re-

lated a case in which the ovum in a tubal pregnancy had become converted into a mole (apoplectic ovum); since then the condition had been generally admitted. Tubal moles could easily be distinguished from uterine moles. The amniotic cavity was eccentric, instead of centric, in consequence of which the thin amniotic membrane was liable to rupture, allowing the embryo to escape; this was why the embryo often escaped discovery after operation. The presence of an embryo, or even of an amniotic cavity, was positive proof of the nature of the mole, but failing them, search must be made under the microscope for chorionic villi. These were characteristic structures, and there was no excuse for confounding them with altered blood-clot. Every blood-clot in the tube was not necessarily a tubal mole, for it was certain that blood-clot might be present in the tube apart from pregnancy. Most specimens described as examples of hæmatosalpinx were really gravid tubes; the term hæmatosalpinx should be restricted to non-gravid Fallopian tubes, distended with blood secondary to occlusion of the abdominal ostium. The retention of the impregnated ovum in the tube usually determined occlusion of the abdominal ostium by the sixth—or, at the latest, eighth—week, unless the ovum happened to be lodged in the ampulla, when of course closure could not take place. The process being a gradual one, so long as the ostium remained patent, the ovum might at any time be extruded through that opening into the peritoneal cavity. When this took place the ovum was invariably in the condition of a mole, and the accident was always accompanied by hemorrhage. To this sequence of events he applied the term tubal abortion. Hemorrhage from a gravid tube, unaccompanied by extrusion of the embryo, constituted "incomplete tubal abortion;" the retention of the embryo in the tube, owing to its being too large to pass through the distal orifice, was a frequent cause of recurrent hemorrhages. The presence of an adventitious opening in the tube-wall did not necessarily imply that the ovum had escaped through the aperture. In tubal abortion the hemorrhage was usually more abundant than in cases of rupture of the tube. Mr. Sutton said he believed that most cases formerly classed as pelvic hæmatocele were really the result of the rupture or abortion of gravid tubes.

At the last meeting of the Medical and Chirurgical Society, Mr. Howse read a paper in which he pointed out the advantages of performing amputation through the thigh in advanced cases of hip-joint disease, when the patient was in a very bad condition. The operation might be performed as a preliminary to, or in some cases instead of, amputation through the hip. By this procedure, the length of the lever having its fulcrum at the hip-joint was reduced and rest thus favored, as less would be required from the muscles controlling the hip-joint. The production of blood of better quality and larger amount would probably be favored by the removal of a mass of tissue acting chiefly as blood-consuming, and very little as blood-producing, tissue. An illustrative case was narrated of a boy of fifteen, with acute tuberculous ostitis of the left leg and ankle-joint, and early mischief in the left hip. He was very ill and emaciated. Amputation through the knee was performed in July, 1879. Great improvement resulted, but suppuration in the hip necessitated excision of this joint rather later, from which he perfectly recovered and had been well ever since.

The Bonacossa Prize.—The subject for the next Bonacossa prize is "Epileptic Psychoses: their Etiology and Clinical Characters." Essays or published works (which must have seen the light subsequently to April 1, 1890) may be written in Italian, French, or Latin, and must be sent to the President of the Academy of Medicine of Turin on or before December 31, 1894. The prize is of the value of 1,950 lire (£78), and if it is awarded to a manuscript essay the money will not be paid till the author presents a copy to the Academy.

DISLOCATIONS AT SIGHT.

To the Editor of the Medical Record.

Sir: In your issue for November 12, 1892, Dr. William Meacher contributes a valuable and interesting article on "Dislocations of the Shoulder," especially in reference to diagnosis. The doctor says that one of the most important diagnostic means we possess is the measurement of the dislocated shoulder, which he thus gives: "Pass a tape measure around under the axilla, and up over the top of the shoulder, about an inch in from the point of the acromion process; and if a dislocation exists you will find that this shoulder measures somewhere in the neighborhood of two inches more in circumference than the sound side."

Dr. Meacher gives Mr. T. Calloway the credit for this point through Bryant. But Agnew in his "Surgery," 1881, while giving the same credit, says that there is a loss of from one to two inches in the vertical circumference. I do not know which author has misquoted. I give the following to show the difficulty of sometimes diagnosing dislocations of the shoulder-joint at sight, and to recall a method:

Some years ago, a bright young doctor returned from the New York Polyclinic, to a country town, blushingly wearing his laurels, and filled with all kinds of surgical technique. Happily the young and resourceful doctor was presented with a dislocation of the shoulder-joint by one of those ruff-diamonds, a village doctor. The ready-method young man could now reflect credit upon himself, and upon the wise men of the East, so he smiled a smile of confidence, and told the old worthy to bring on his man. He would reduce the dislocation by the "New York method," quicker than a gnat could wink.

The patient was told to lay down upon a table, the manipulator placed himself between the dislocated shoulder-joint and the body of the patient, with his back toward the axilla, grasped the patient's hand, and firmly held it against his own hip, while he strongly rotated his own body, and presto, the dislocation was reduced. Apparently he had perfectly triumphed, and with a burst of pride requested his senior to behold the shoulder. The elderly doctor alternately looked at the shoulder, and at the thaumaturgist, and all was symmetry and even pristine beauty about the shoulder. Looks of congratulation, momentary happiness among the doctors. Meanwhile the patient had been passive, but was much impressed, for it was very shortly discovered that the wrong arm had been manipulated.

Thomas R. Evans, M.D.

Burlington, Ia.

The Side to Sleep on.—"Which side should I sleep on, doctor?" he inquired.

"In winter or summer?" asked the doctor, rubbing his chin thoughtfully.

"What's that got to do with it?" exclaimed the patient, half angrily.

"A great deal," responded the doctor, mysteriously.

"I don't see it."

"Of conrse you don't," said the imperturbable; "if you did you wouldn't be here asking me questions about it."

"Go ahead, then," said the patient, sitting back resignedly.

"Well," continued the doctor, "in winter, when it is cold, you should sleep on the inside; but in such weather as this you should sleep on the outside, in a hammock with a draught all round it, and a piece of ice for a pillow. Two dollars, please."

Accidents to Mountain Climbers.—The *Tourist Zeitung* publishes a list of Alpine accidents for 1892. There were 32 fatalities in all, 26 having occurred in ascents without guides, and 6 with guides. Twenty-six were tourists and 6 were guides. Ten were caused by attempts to gather edelweiss.

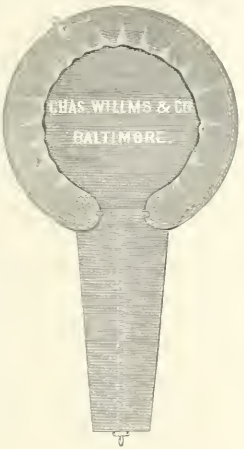
New Instruments.

CONFINEMENT ON THE OBSTETRIC PAD.

By HOWARD A. KELLY, M.D.,

PROFESSOR OF GYNECOLOGY AND OBSTETRICS IN THE JOHNS HOPKINS UNIVERSITY, BALTIMORE, MD.

WHILE the great profits which have accrued to modern medicine from bacteriological studies are realized most fully in the obstetrical field, one notable relic of barbarism remains, that is, the extensive soiling of the bed during parturition. That the bed on which the patient lies should soak up the discharges, from the rupture of the waters down to the gush of blood following the delivery of the placenta, is a practice in direct contradiction to the spirit of all modern surgical work. The discharges themselves are physiological and must come, the objection is to our preparation for receiving and disposing of them, by allowing the bed and bedding and patient's clothing to become the receptacle, an accidental concomitant which is repulsive to the antiseptic conscience of every rightly trained obstetrician.



Obstetric Pad, open.

When living in Philadelphia I saw and heard of cases in which the amount of discharge at the confinement was sufficient to saturate half the bed, and even percolate through the straw mattress, wetting the floor. Among the poor, the old mattress and bedclothing thus soiled cannot often be replaced, and a serious embarrassment confronts the physician, who recognizes the subsequent liability to fermentation of such highly organized albuminous fluids. The sense of culpability in thus leaving a patient lying in a pool of decaying secretions constituting a constant menace to her life, is one distressing to bear.

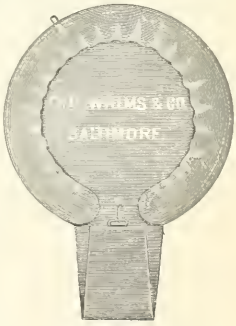
To obviate these dangers every earnest obstetrician has adopted certain precautions for the protection of the bed, limiting the spread of the discharges. To this end, rubber sheeting, prepared absorbent pads, and even newspapers have more recently been pressed into service as protectives, in place of pieces of old cloth and rags and carpet, once familiar articles in the lying-in room; still, however, the nuisance is not entirely abated. I have overcome this evil for several years by conducting all my confinements on a specially devised rubber obstetric pad, a rubber sheet with an inflatable rim which protects the bed, while an opening is left on one side, allowing free discharge of fluids into a bucket or jar placed by its side. This is thus similar in general design to my ovariotomy, perineal, and general surgical pads now in wide use.

The first pad devised for this purpose has been in constant use by some of my friends, notably Dr. Robert L. Dickinson, of the Long Island College Hospital, and Dr. Hunter Robb, who has dwelt upon its advantages in an article published in the *Medical News* of Philadelphia, December 29, 1888. This pad was constructed with the intention that fluids should at once discharge as they escaped from the patient over the apron of the pad, hanging down the side of the bed, and into the bucket on the floor. Experience taught me, however, that the inequalities of some beds were so great that no escape of the discharges took place in this direction, the fluids, on the contrary, remained in the pad, and ultimately even overflowed into the bed.

After some further experimentation, I have settled upon the improved obstetric pad shown in the figures accompanying the text. This has a large inflatable rim, big enough to hold all the parturient discharges without overflowing. At the end of the labor it is picked up, and the blood and amnion with the placenta and membranes gravitate into the bag-like receptacle, which replaces the open apron to the first pad. The pad is then carried into the bath-room and emptied of its contents by letting down the hook which makes a bag of the tube while it is in use, it is then washed clean under a strong stream of water from the faucet. In using the pad, the patient will be most comfortable and the progress of labor can be best observed while she is lying upon her back, with the upper part of the sacrum resting on the inflated rim, thus leaving abundant pad-surface below the buttocks and between the patient's legs for the reception of fluids, child, and afterbirth. It is a mistake to adjust the pad higher up so that the rim rests under the small of the back; it is not serviceable in this position, and by no means so comfortable.

Patients but rarely object to this new accessory to the obstetric wardrobe. I have often heard them express themselves as relieved by the constant elastic pressure made by the rim upon the lower part of the back. A little persistence and assurance will overcome any prejudice at the outset.

Before slipping the pad under the patient, her nightgown should be pulled well up to the thoracic region to clear the rim, she then raises herself upon her heels and shoulders while the warmed pad is placed under her in position as shown in the figure. It should not be brought into use until the bag of waters is about to be ruptured. After the first escape of the larger amount of the amnion, the pad may be removed, and further occasional gushes of fluid caught by large pledgets of absorbent cotton, placed under the vulva, and renewed from time to time, until just before the birth, when the pad, cleaned, and warmed, should be again slipped under the patient and allowed to remain in position until the placenta and clots following have been discharged.



Obstetric Pad, closed.

When labor is thus completed assist the patient in elevating her buttocks while the pad is drawn out, and the buttocks, vulva, and thighs wiped clean with a sterilized towel or absorbent cotton, and a pledget of sterilized absorbent cotton placed beneath the vulva. She is thus allowed to rest at once and without the tedious annoying changes otherwise necessary, not to speak of dangers obviated by greater cleanliness, and a minor but still important item, the saving in the wash.

The greatest inconsistency in our obstetrical practice is thus simply and conveniently removed.

A Queer Kind of a Maid.—A poetical certifier to the merits of a much advertised preparation, states that in his practise "it accompanies the maid from her virgin couch to her lying-in chamber, assuaging the perplexities of maidenhood and easing the trials of maternity." We have nothing to say against the perplexities of maidenhood, for we have no doubt they are as perplexing as most perplexities, but we really think it is improper for a maid to have a lying-in chamber; she ought to be content with her virgin couch.

A NEW SHIELD FOR THE PROTECTION OF EYES AFTER CATARACT OPERATIONS.[1]

By THOMAS J. McCOY, M.D.,

HOUSE SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, NEW YORK; MEMBER OF THE SOUTHERN CALIFORNIA AND LOS ANGELES COUNTY MEDICAL SOCIETIES.

THE number of injuries which occur to the eyes for the first twelve days after cataract operations, by accidental knocks or bumps, while asleep or awake, naturally suggests some form of protection to the ophthalmic surgeon, as it has to myself, after observing the results of seven different traumatisms thus produced during my service in the Manhattan Eye and Ear Hospital, so far.

Upon investigating medical literature, and conversing with experienced men on this subject, I find evidences of many other cases injured in the same way, though little accomplished and accepted as a suitable appliance for the mechanical protection, that will prevent the danger and be tolerated until the eyes are safe.

Surely, enough accidents have occurred to prompt us in carrying out a systematic protection in order to secure the complete union of the flaps by allowing nature rest and without disturbance in her efforts in the restoration of the corneal tissue.

Eye-shield.—A, figure-of-eight bandage; B, tapes which hold the shield.

These accidents occurred from the second to the eighth day. The eye was struck with the hand and wound reopened in four cases. Of these, three had prolapse of iris, the other iritis. Another was injured by the patient striking his eye on the corner of the bed, and the other two rubbed their eyes, causing conjunctivitis.

In July, Dr. Kirkendall, of Ithaca, N. Y., while visiting us, reported a case of his who knocked his eye entirely out on the tenth night. As to the protection so far tried, the most effectual is that which was practised by Graefe, viz.: The "handcuffing" or tying the hands to the side of the bed. This treatment was practised here about eight years ago for a while, but finally abandoned because of the serious objections raised by the patients, as it deprives them of the use of the hands, rendering them entirely helpless, and requires the constant attention of a nurse.

For a more desirable safeguard, I present the accompanying shield, which presented itself to my mind, and is shown in the accompanying cut, and has proven itself to be an efficient protection in the last twenty-six cases of cataract operation in the hospital, and one each in the private practice of Drs. Roosa and Webster.

Each ophthalmic surgeon to this hospital has ordered its use on all cases after cataract operations, since its introduction in July, with the following results: There has been no traumatisms or prolapse of iris while it has been worn, excepting in one of Dr. Webster's, and in this case it was taken off at the end of twenty hours, as the woman was nervous and thought the shield might have something to do with it.

In thirty hours afterward the bandage was removed for the first time. Wound found opened and iris prolapsed. Here it is impossible to tell whether this prolapse occurred before or after the removal of the shield. One of Dr. Pomeroy's cases wilfully tore off the shield and dressings on the fourth night, though no injury was found the next morning. As he was unruly it was advised to leave off the shield, fearing he might hurt his eye. The next night he again tore off the bandage and cotton. A prolapse was found. One of Dr. Webster's cases hurt his eye on the fifth night, while the shield was off.

Only two cases have objected to wearing it, while several have expressed a desire to have it on, when assured they were less liable to injury. One lady, especially, a patient of Dr. Roosa, expressed herself as being unable to sleep without it was on, for fear of injuring her eye.

A private case of Dr. Webster's forgot to replace it on the tenth night, when she accidentally ran her finger in her eye, though doing but little damage; replaced the shield, and expressed herself to the doctor that it was "a great invention."

The shield is very light in weight, applicable to any face, fits neatly and comfortably around the orbit, easily kept aseptic, and if struck the force is conveyed to the bony orbit. It is simple in structure, made of German silver wire, nickeled, oval in shape, with the convexity outward.

The base wire is one-fourteenth of an inch in diameter, and balance one-half that size. The tapes should be kept neatly tied as shown, and united at the junction behind with small safety-pins. The eight rafters which are neatly soldered at equal distance on the base, convexing, then uniting at the apex with the rings soldered at equal distance on these at right angles, as shown, make the shield a safe protection to the eye from even hard knocks, and it can be worn while either eye is bandaged, allowing the patient to see through the meshes with the fellow-eye. The cotton can be retained in the concavity of the shield and bandage—or adhesive strips which are used by a few to retain the cotton, can be dispensed with. I advise the shield to be worn from the tenth to the twelfth day, especially at night, as less vigilance may account for the greater number of accidents after the first two or three days.

Dr. Prout, of Brooklyn, has introduced as a shield a light piece of wire gauze, about four by eight, to be applied over the bandage. It seems the least tap or pressure on it would convey the force through the dressing to the eye, therefore thwart its good intentions.

Dr. Frothingham has produced a mask which seems a good protection if it will be retained by the patient. It is heavy and bulky, and will not be retained long enough, I am told.

From past experience, it seems the conservative ophthalmic surgeon ought to insist on the protective vigilance from external violence until the eye is out of danger.

MANHATTAN EYE AND EAR HOSPITAL, NEW YORK.

[1] Presented by invitation to the New York Ophthalmological Society, at their regular meeting, November 14, 1892.

Patent Medicines in Great Britain.—The British must be great consumers of patent medicines, for during the past year the revenue derived from the three-halfpenny stamp upon patent medicines amounted to $1,200,000. Licenses for the sale of patent medicines have increased 1,340 in England and 111 in Scotland.

CHOLECYSTO-INTESTINAL, GASTRO-INTESTINAL, ENTERO-INTESTINAL ANASTOMOSIS, AND APPROXIMATION WITHOUT SUTURES. (ORIGINAL RESEARCH.)*

BY J. B. MURPHY, M.D.,

CHICAGO, ILL.,

PROFESSOR OF CLINICAL SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO; PROFESSOR OF SURGERY, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO, AND PRESIDENT OF, THE MEDICAL STAFF OF COOK COUNTY HOSPITAL; ATTENDING SURGEON TO ALEXIAN BROTHERS' HOSPITAL; VICE-PRESIDENT OF NATIONAL ASSOCIATION OF RAILWAY SURGEONS, ETC.

MR. PRESIDENT AND GENTLEMEN: Intestinal surgery occupies a very advanced place in the category of great surgical questions of the present day. Medical literature teems with reports of successful cases operated on, and not a few of the disasters are also placed on record. All over the world investigators are trying to solve the many perplexing problems that accident and disease of the gastro-intestinal tract present to them for consideration. That this subject has had such exhaustive consideration during the last decade, and that it is still a theme for spirited controversy and discussion, carries with it the implication that many vital points are yet unsettled and need further investigation, experimental and clinical. The results of experiments on lower animals have been conducive to great improvement, both in principle and technique of treatment of intestinal lesions in the human subject. Fair results are obtained in the treatment of bullet wounds of the intestines at present. At least an effort is made by the surgeon to repair the injury.

The question above all others on which the profession is divided is, "What are the best means and methods of producing agglutination of surfaces and preventing subsequent contraction at the point of adhesion?" If means can be devised—1, to hold the surfaces in contact; 2, while in contact, to produce a speedy and permanent adhesion of the surfaces; 3, to keep an opening sufficiently large for the free passage of intestinal contents; 4, to produce, as a result, a cicatrix that will not contract to any great extent, and by the contraction produce complete or partial obstruction—we will have overcome the great barriers that still remain between us and ideal success in intestinal surgery.

The marvellous ingenuity displayed in plans devised for intestinal approximation and anastomosis is worthy of the greatest success, and that success would have been realized were it not that some of the following complications occurred: "The suture was imperfectly applied; the bowel sloughed through at line of suture; the induced invagination increased after the operation until complete obstruction was produced; openings in the bone-plates and disks were not in apposition; the ends of the bone-plates caused pressure, atrophy, and perforation; the catgut sutures were too rapidly absorbed; lastly, and with appalling frequency, prolonged operation produced fatal shock," and many other well-known obstacles, not necessary to mention here, intervened

To overcome these obstacles and thus lessen the risk to the life of the patient, I have devised a mechanical means to dispense with the need of sutures, the necessity of invagination, the possibility of non-apposition, the sloughing through of disks, the digestion of the catgut, the almost insurmountable difficulties of technique of operation, the prolonged and fatal exposure of the abdominal contents, and the protracted anæsthesia. How much I have accomplished by my labor I desire you to be the judges, after I have demonstrated to you the results of my experiments, and performed for you a gastro-enterostomy and an end-to-end approximation of intestine by means of the device I here present to you, to be known as the Anastomosis Button.

The buttons are made in three sizes. A button consists of two small circular bowls (Fig. 1); size No. 2 measures as follows: Diameter, 23 mm.; depth, 8 mm. There is "sweated" into a circular opening, 12 mm. in diameter, at the bottom of one bowl, a cylinder 15 mm. in length, with female screw thread on its entire inner surface. The cylinder extends perpendicularly from bottom of bowl. There is an opening in the male bowl in which is "sweated" a similar and smaller cylinder of a size to easily slip into the female cylinder. There are two brass springs soldered on either side of the inner surface of the

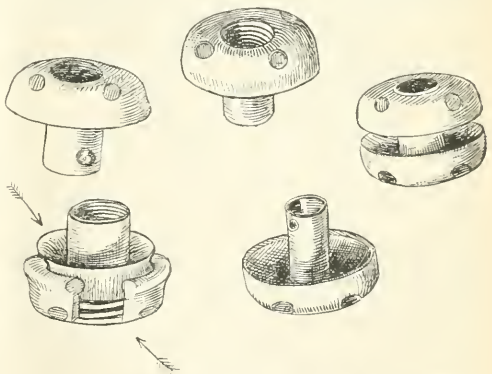

FIG. 1.—Appearance of Button with and without Spring-up Attachment.

lower end of the male cylinder, which extend almost to the top, where small points of them protrude through openings in the cylinder; these points are designed to catch the screw-thread, when the male cylinder is pressed into the female cylinder, and thus hold the bowls together at any point desired. To separate them again they are simply unscrewed. A small brass ring, with a thin though not cutting edge, to which is attached a wire spring, is placed in the male bowl and retained in position, projecting one-eighth of an inch above the edge of the bowl. This is held up by the wire spring, and is there for the purpose of keeping up continuous pressure until the entire tissue between the edges of the bowls is cut off. This spring attachment is absolutely necessary only when the stomach is operated on. There are four openings, 5 mm. in diameter, in the side of each bowl, for the purpose of drainage. By this, it will be seen, we have two hemispherical bodies held together by invaginating cylinders (Fig. 1). These hemispheres of the button are inserted in slits or ends of the viscera to be operated on. A running thread is placed around the slit in the viscus, so that when it is tied it will draw the cut edges within the clasp of the bowl. A similar running thread

* Read before the Mississippi Valley Medical Association, October 15, 1892.

is applied to the slit in the viscus into which the other half of the button is inserted, and the bowls are then pressed together. The pressure atrophy at the edge of the bowl is produced by the brass ring supported by the wire spring. The opening left after the button has liberated itself is the size of the button.

This differs from all other previous devices in the following particulars or combinations thereof: 1, It retains its position automatically; 2, it is entirely independent of sutures; 3, it produces a pressure atrophy and adhesion of surfaces at the line of atrophy; 4, it insures a perfect apposition of surfaces without the danger of displacement; 5, it is applicable to the lateral as well as to the end-to-end approximation; 6, it produces a linear cicatrix and thus insures a minimum of contraction; and 7, in the extreme simplicity of its technique, which makes it a specially safe instrument in the hands of the everyday practitioner as well as the more dexterous specialist. We will now consider its application.

Cholecysto-Enterostomy. *Gall-bladder and Intestinal Fistula—Gall-bladder and Intestinal Anastomosis.*—The idea of this operation was suggested by nature in establishing pathologically a fistula between the gall-bladder and the intestine. In this way the surgeon was guided to the best means of relief where an occlusion of the duct was produced by the pressure of an impacted concrement, a neoplasm, a cicatricial band, or any pathological lesion which would render the common duct impervious. While nature had thus blazed the way, surgeons were slow to take advantage of its suggestion. The first one to advise this method was my late lamented friend, von Nussbaum, of Munich, 1880. He expressed himself in the following words: "When the escape of gall through the natural duct is no more possible, the question arises if we cannot make an artificial connection between the gall bladder and intestine through which the gall can again escape into the intestinal tract," etc.[1]

The first to work out a feasible plan for the attainment of this ideal result was von Winiwarter.[2] Between the 20th of July, 1880, and the 14th of November, 1881, he had under his care a man, with occlusion of the ductus choledochus, on which he operated six different times, and finally succeeded in establishing a fistula between the colon and the gall-bladder, after sixteen months of labor. His original plan was to perform the operation in two sittings, but all sorts of difficulties beset his way. It is wonderful what energy and persistence both the operator and patient showed to overcome all impediments. After the publication of his most difficult task it was six years and a half before a surgeon was found who had the courage to undertake a similar operation, when Kappeler[3] undertook to follow in the footsteps of Winiwarter, but to do the operation in one sitting.

In the meantime there were several experiments made on animals, with the hope of discovering a means of making a communication between the gall-bladder and the intestine at one sitting. Gaston, in 1883, experimented on five dogs, with elastic suture, which was so placed as to approximate the gall-bladder and intestine, and around this a row of serous sutures to protect the peritoneum. He hoped by the elastic pressure to produce an atrophy and establish a fistula. The results were unfavorable. In one the sutures sloughed through; two ended in peritonitis; one in abscess between coils of intestine—here the ligature sloughed through into the gall-bladder, and left but an extremely small opening; and in one, at the end of the eleventh day, there was found sufficient adhesion and the fistula was established, the ligature being found in the intestine. In 1884 he used a similar ligature on a young dog, in the same manner, with a good result. In 1886 he made several similar experiments, with the addition of ligating the common duct, but the dogs only lived a few days, dying of extensive gall-infiltration in the liver.

G. Harley suggested the approximation with the formation of fistula from the gall-bladder to the intestine by means of sutures and caustic potash. He arranged a number of sutures in a small circle, about the size of a dollar, holding the gall-bladder to the bowel, but before completing the circle mentioned, cauterized the centre with caustic potash, then completed the circle with sutures, and in that way hoped to produce a fistula of the gall-bladder and have an adhesion by plastic exudation surrounding it. He claims to have had good success in animals.

Colzi, in 1883, put in a similar circle of sutures as Harley, but before the final suture made an incision in the centre into the gall-bladder and duodenum, also ligating the choledochus. The animals tolerated the operation without any apparent disturbance in the digestive functions.

De Page, in 1887, performed the same experiment as Colzi, on three dogs, without ligating the choledochus. In one the suture sloughed through; another died of peritonitis; the third was killed at the end of six weeks and showed an atrophy of the gall-bladder, but no fistula.

Finally, Dastre,[4] in his communication to the Physiological Congress at Basel, in 1889, published his experiments, wherein he succeeded in uniting the gall-bladder to the intestine for the purpose of studying what effect it would have on digestion. Of this I will speak later.

So that we see to the date above mentioned experiments represented three different types: 1st, The formation of fistula by chemical destruction; 2d, by pressure atrophy—the elastic ligature; 3d, careful suturing, with subsequent incision within the circle produced by the sutures.

Up to July, 1890, there were nine "one sitting" operations performed tor the establishment of a gall-bladder and intestinal fistula in the human subject; the first by Monastyrski, May 4, 1887.[5] The incised gall-bladder and jejunum were approximated by two rows of sutures in serous coat. The patient died on August 4th. The fistula was found patulous. Second, Kappeler,[3] on July 6, 1887, after incision of gall-bladder and duodenum, approximated with a suture of serous and mucous coats, after the method of Woelfler—recovery. Third, Socin,[6] on November 19, 1887, after incision of gall-bladder and intestine, united them with sutures of mucous and serous coats—recovery. Fourth, Fritzsche,[7] on April 24, 1888, operated for impaction of gall-stone in choledochus, united incision of gall-bladder and intestine with catgut sutures of mucous coat and silk sutures of serous coat. Patient died on May 4th. Large amount of blood in peritoneal cavity. Fifth, M. Robson,[8] on March 2, 1889, after incision of gall-bladder and colon, united mucous and serous coats with chromicized catgut sutures—recovery. Sixth, Terrier,[9] August 13, 1889, after incision of gall-bladder and duodenum, approximated with two rows of sutures, put in drainage-tube, and sutured the gall-bladder to abdominal wound—recovery. Seventh, Courvoisier,[1] March 28, 1890, secured a portion of the gall-bladder, and with serous sutures approximated it to the colon, after having made a ductotomy of choledochus and removed several stones with curette from the ductus hepaticus—recovery.

The priority of the operation certainly belongs to Monastyrski, for he performed his operation about a month before Kappeler, but did not publish it until eleven months after the operation. Of the seven operations performed, four were for carcinoma of the head of the pancreas, one for carcinoma of the duct at its orifice, and two were for impaction of gall stones—those of Terrier and Courvoisier. The technique in all of the above operations was somewhat similar, the suture being used as the means of approximation, Terrier using a rubber tube to keep the opening patulous, which was passed on the eighth day. The seat of the operation in Terrier's case was the duodenum; in Monastyrski's, the jejunum, 2 m. below the duodenum; in Kappeler's, 226 ctm. above the cæcum; in Fritzsche's case 3 m. below the pylorus.

There remain the cases of Bardenheuer,[11] who per-

formed two operations where he united the gall-bladder to the duodenum with an elastic suture in the centre and a single row of silk sutures around it, expecting that the elastic suture would produce a pressure atrophy, and that a fistula would remain. The first case—impacted gall-stone—terminated fatally at the end of four weeks, and the fistula was not yet established, nor had the gall-bladder adhered to the intestine, a biliary fistula opening into peritoneal cavity. The second, he writes to Terrier, was done in the same way, with the same result. To this list, taken from Courvoisier, may be added two by Czerny,[10] of whom one died of hemorrhage and the other survived the operation, and my two, of which I will speak later, making, up to date, in all, thirteen cases of cholecysto-enterostomy. Of these four died as the result of operation—Fritzsche's, two of Bardenheuer, and one of Czerny; five died as a result of the malignant diseases from which they were suffering; and four survived—Terrier's, Courvoisier's, and two of mine.

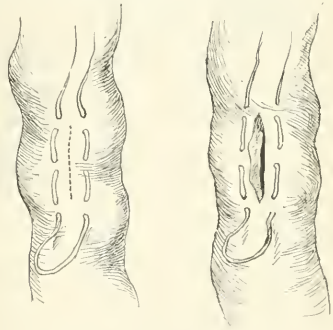
Since writing the above I find a case reported, July 3, 1892, by Dr. E. Lambotte, of Schaerbeek, Belgium,[13] in which he had an external biliary fistula following cholecystostomy. He drew out a piece of the colon through an incision in the abdomen close to the fistula, and then applied Dupuytren's enterotrite in the manner that that author used it for the repair of an artificial anus, finally performing a plastic operation to close the external opening in all three operations. The patient survived the very tedious operative procedures. This case does not belong with the class of "one sitting" operations. Also, a case by Korte, reported to the Berlin Medical Society, May 27, 1891, in which the suture was used for approximation.

The various operators, in commenting on the technique of the operation, all agree that it is one of extreme difficulty; and, while the experience of the others is not as trying as that of Winiwarter, it was always most difficult of performance and occupied an hour or upward to complete the operation.

While reading of the great difficulties experienced by the operators mentioned in performing this operation, I realized that the profession was sorely in need of some more simple and perfect means for the approximation of the gall bladder and the intestine; and, after trying several devices, I succeeded in producing and perfecting this anastomosis button, which I think fulfils all of the indications. The button is inserted in the following manner:

An incision is made from the edge of the rib, two inches to the right of, and parallel to, the median line, extending downward three inches. The gall-bladder is drawn into the wound, also the duodenum. The duodenum is cleared of its contents by gentle pressure with finger. My short intestinal compression forceps are placed upon the duodenum to prevent the escape of gas and fluids after the incision is made. A needle with fifteen inches of silk thread is inserted in the duodenum, directly opposite its mesentery and at a point near the head of the pancreas. A stitch is taken through the entire wall of bowel, one-third the length of the incision to be made. The needle is again inserted one-third the length of the incision from its outlet, in a line with the first, and brought out again, embracing the same amount of tissue as the first (Fig. 3). A loop three inches long is held here, and the needle is inserted in a similar manner, making two stitches, parallel to the first, in the reverse direction, and one-eighth of an inch from it, coming out at a point near the original insertion of the needle (Fig. 2). This forms a running thread, which, when tightened, draws the incised edge of the bowel within the cup of the button. In the gall-bladder a similar running thread is inserted. An incision is now made in the intestine, two-thirds the length of the diameter of the button used. The button is slipped in, as I will show you in my demonstration, the running string tied, and the button held with the forceps. The contents of the gall bladder are withdrawn with an aspirator. An incision is then made in the gall-bladder the same length, and between the rows of sutures, the button is inserted in a similar manner, and the running string tied. The serous surfaces to be approximated are scraped with the edge of a scalpel. The forceps are removed and the button is held between the fingers and pressed together (Fig. 4). A sufficient degree of pressure must be used to bring the serous surfaces of the gall-bladder and intestine firmly in contact and compress the tissues. The elastic pressure of the spring cup of the button produces a pressure atrophy of the tissue embraced within the cup, and leaves an opening as large as the button, the button dropping into the bowel and being passed through the intestines.

It takes about as long to describe the operation as to perform it. The time occupied with the first lady on whom I operated was eleven minutes, from the entering of the peritoneal cavity until the closing of the same. On dogs I was from eleven to eighteen minutes in performing the operation, the latter time being on the first dog, before I had made the various improvements in the technique and button. The operation is more difficult to perform on the dog than on man, as it is more difficult to bring the gall-bladder into the wound.



FIGS. 2 and 3.—Showing Running Thread before and after Incision in Bowel.

To show that this operation is one that the busy surgeon will be frequently called upon to perform, now that the technique is so simple, I have only to remind you of the number of cases of chronic jaundice from obstruction to the common gall duct, requiring some operation for relief, and to draw your attention to the defects of the operations now in vogue, namely, the unpleasant and sometimes dangerous sequence of cholecystostomy, an external biliary fistula, which may of itself be a menace to life, and require a second operation even more critical than the first, as is shown in the following reports by Courvoisier; also the difficulties and dangers of cholecystectomy.

The effect of a permanent fistula of the gall-bladder and constant escape of bile secreted, as frequently follows cholecystostomy, is different, depending, first, on the quantity of bile that escapes from the opening, and, second, what proportion is admitted into the intestinal tract. This fact has been lost sight of by many of the surgeons that have operated, and had an external fistula remain, which accounts for the great differences of opinion as to gravity of biliary fistula. Where the fistula of the gall-bladder only allows a portion of the bile to escape, the patient and animal, as in Dastre's experiments, can live without suffering from the loss; that is, they are capable of digesting with a much smaller quantity of bile than they naturally excrete. But if we let the entire quantity of bile escape through a fistula, the patient soon succumbs. This is thoroughly demonstrated by the twelve cases collected by Courvoisier.[1] In one of these cases, reported by Krumptmann,[12] the average daily quantity of bile escaping through a fistula was 230

gm.; still the patient lived eight years in this condition. Where such an able authority as Courvoisier classes this with his cases in which there was an escape of the entire quantity of bile, it may appear presumptuous to question the propriety of placing it in that class; but as the quantity is so much below the average given by physiologists, and as the effect on the patient was at such variance with the more reliable cases, I must ask you to analyze it. For example, some estimates of the quantity daily excreted are—by Wittich, 532 c.c.; by Westphalen, 453 to 266 gm.; Ranke, 652 c.c.; Murchison, 40 ounces. When compared with that given by Krumptmann, we are certainly justified in doubting its reliability, and in not placing it with unquestionable cases. All patients died where the entire quantity of bile secreted escaped through the fistula, and where a large quantity escaped the patients became emaciated and sick. Therefore a safe means of allowing the gall to re-enter the intestine should be welcomed by the surgeon and patient. This operation will produce the same revolution and favorable change in the surgery of the gall bladder that the intra-abdominal treatment of pedicles did in the treatment of tumors of the uterus and its appendages.

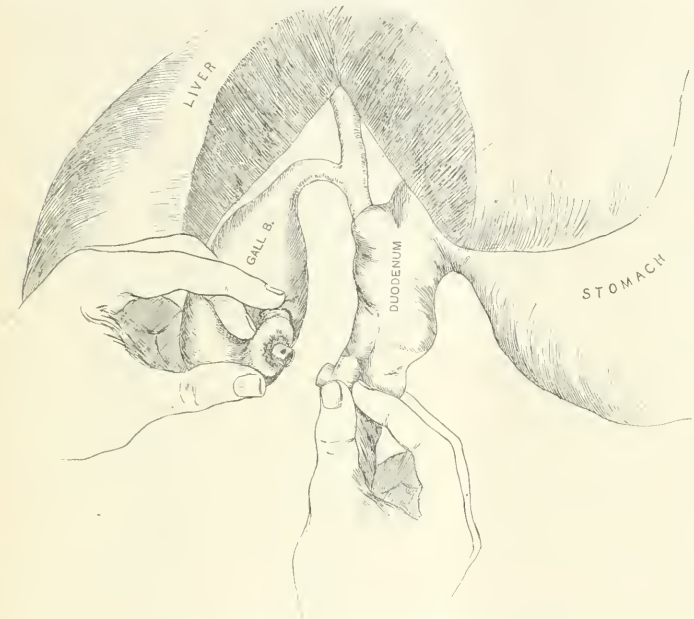


Fig. 4.—Button as Held when Pressed Together Performing Cholecysto-enterostomy.

The following experiments were performed on the gall-bladder:

Experiment 4.—June 5, 1892; male dog, weight 70 pounds. Abdomen shaved, incision three inches long, in the median line. The duodenum was easily reached—as it passes from the end of the stomach close to the liver—and brought into the wound; the gall-bladder was also drawn forward and held with the forceps. The incision was made in the gall-bladder and one-half the button inserted; a running thread was placed around the circumference of the opening, and the thread tied; the gall bladder was allowed to recede. An incision was made into the duodenum, parallel to the bowel, opposite its mesentery, large enough to admit the button. A running thread was sewed into the edge of the incision, one half of the button inserted, and the running thread tied. The button was pressed together. The approximation was perfect; time, eighteen minutes. The dog had no unpleasant symptoms until the third day, when he appeared sick and refused to drink. On the fifth day he was much improved, and on the sixth he had completely recovered; he was playful as if nothing had happened to him. On July 10th, thirty-five days after the operation, he was killed. The button had escaped, and the opening was found large enough to admit the little finger from the gall-bladder into the intestine (Fig. 5). There was no food or hair in the gall-bladder, as a valve was formed on the intestinal side of the opening by two folds of the mucous membrane closing over it, permitting the bile to flow out, but preventing the entrance of anything from the intestine. This valve (Fig. 5) could not have been more perfect had it been prearranged. The gall-bladder was very much contracted. You can examine the result in specimen.

Experiment 5.—June 12, 1892; black male hound, weight 55 pounds. Operation performed the same as in Experiment 4. Some bile escaped into the peritoneal cavity. The attachment of the gall-bladder to the liver was torn slightly in the effort to bring it further forward into the opening. The button worked admirably. Time, sixteen minutes. The dog did not suffer in the least after the operation, being playful and able to eat at all times. August 22d he was killed. A perfect union was found between gall-bladder and duodenum. The gall-bladder had contracted to about the size of the common duct. The opening between intestine and gall-bladder would admit the end of the little finger. A valve similar to that described in Experiment 4 was found. Neither hair nor food was found in the gall-bladder.

Fig. 5.—Opening with Valve, after Cholecysto-enterostomy, on Intestinal Side.

Experiment 7.—June 14, 1892; St. Bernard, female, weight 100 pounds. Cholecysto-gastrostomy, operated in the same manner as in Experiment 4, only using the stomach in place of the intestine. No escape of bile or gastric fluid into the abdominal cavity. A little difficulty experienced in approximating the ends of the button on

account of the thickness of the wall of the stomach. Time, seventeen minutes. Dog sick the following day, would not eat or play. On the 17th all symptoms had disappeared. August 9th, killed dog; found gall-bladder firmly united to the stomach; little finger could be inserted into the stomach from the gall-bladder (Fig. 6); there was neither food nor hair in the gall-bladder, which was somewhat contracted. No cholecystitis nor cholangitis. The dog did not seem to suffer any inconvenience from the gall passing into stomach.

FIG. 6.—Opening in Stomach after Cholecysto-gastrostomy.

Experiment 13.—July 7, 1892; black dog, weight 65 pounds. Cholecysto-enterostomy. The gall-bladder was brought into the opening without lacerating its attachment to the liver, and the running thread inserted; operation completed as above. Some escape of gall into the peritoneal cavity. Time, sixteen minutes. Killed dog, August 23d; found the gall-bladder contracted to a tube not much larger than the ductus cysticus; opening into intestine admitted the little finger. Valve formed by fold of intestinal mucous membrane. Water would flow freely from the side of the gall-bladder into the bowel, but would not flow from the bowel into the gall-bladder on account of this valve. Neither hair nor food in the gall-bladder.

Experiment 18.—August 2, 1892; white female dog, weight 95 pounds. Cholecysto-enterostomy; ligature of common duct; operation otherwise as above. Time, eleven minutes. Result examined August 6th. Found a perfect adhesion of gall-bladder to bowel; button in position. Hair and food in gall-bladder.

Experiment 21.—August 30, 1892; red and white hound, weight 90 pounds. Cholecysto-enterostomy. Time, fourteen minutes. No difficulty experienced; the dog had no unpleasant symptoms following. Killed on September 14th; found perfect union of gall-bladder to bowel. Partial atrophy of tissue in clasp of button; button in position; hair and food in gall-bladder; gall-bladder about the normal size. This dog was killed thus early to find what changes would take place in fourteen days.

Report of Cases.—CASE I.—A. Q——, aged thirty-five, female; admitted to the medical department of Cook County Hospital, May 27, 1892. Transferred to the surgical division of the hospital, June 10, 1892, and came under my care. Gave the following history: During the last fifteen years has had stomach troubles; pain and tenderness in the epigastrium; the attack would last from two to four days, was almost always accompanied by vomiting, never by jaundice. Had pain in back since child birth; suffered from chronic constipation. One of these attacks was accompanied by jaundice for the first time, December 14, 1891. At that time had constant and intense pain for twelve hours, and an aching pain and tenderness in the epigastrium for two months following it. Jaundice cleared in about two months. During the past few months the attack of stomach trouble would last from twelve to twenty-four hours. In February the present attack began, accompanied by jaundice and severe pruritus, which has been constant from that time up to date. These symptoms increased in severity up to the time she was admitted into the hospital. While in the medical department her jaundice was constant; her mental condition became very much impaired and her emaciation rapidly increased.

Condition when Admitted to the Surgical Department.—The patient intensely jaundiced; very much emaciated; has a point of tenderness in the right hypochondriac region just below the margin of the rib; no tumor to be felt. The urine contains a large quantity of bile, no albumin. The patient suffers from considerable mental derangement, very slight elevation of temperature.

June 11th.—I decided to perform cholecysto-enterostomy by means of my anastomosis button, which I had used for the first time on a dog six days previous. An incision three inches long was made, three inches to the right of the median line, extending directly downward. The gall-bladder was found distended, non-adherent, and contained a large number of small calculi. Duodenum and gall-bladder were both drawn into the wound; an incision was made in the duodenum and half of the button inserted. A running thread was put in the gall-bladder, an incision made, and the other half of the button inserted. The gall-stones were not removed. There was considerable escape of gall, as gall-bladder was not aspirated before putting in the button. The button was then pressed together without any difficulty, and the mass dropped into the abdominal cavity. Time from the opening of the peritoneum until the closing of same, eleven minutes. After the operation the patient showed no unpleasant symptoms; temperature at no time exceeded 100° F., and in fourteen days from the operation she was allowed to walk about the ward. The jaundice rapidly disappeared, and three weeks after the operation there was no trace of bile in the urine. The patient was of a very hysterical temperament after her mental condition improved; she noticed that she was an object for observation and became so erratic that we could not control her at the hospital and were compelled to discharge her five weeks after the operation. Up to that time she states that "she has not passed the button." She was appearently well in every particular.

October 28th.—Patient was examined by Dr. H. R. Wittwer. He found the jaundice had not returned; there was no bile in the urine, and the patient was in excellent health. He could not ascertain whether she had passed the button or not.

The following case was referred to me by Dr. Hoelscher, who with Drs. Wiener and Lee assisted me in the operation.

CASE II.—Mrs. B——, aged thirty eight, widow, has three children. Parents still alive, aged seventy-six and seventy-four respectively. Brothers and sisters well; no history of any hereditary disease.

Dr. Hoelscher saw the patient for the first time October 7, 1892, and found her as follows: "Healthy, well nourished appearance; pain of sudden onset in the epigastric region, and from this point it gradually extended over the whole abdomen. She had vomited the contents of the stomach and some bile on two occasions after the seizure with pain. Bowels were constipated and had been in this condition two or three days before the seizure. Vesical tenesmus and diminished quantity of urine. Gave no history of any previous pain, gastric disturbance, jaundice, or colics."

On examination found a tumor in right hypochondriac region, extending downward into the iliac region and terminating in a rounded smooth end; could be distinctly felt in lumbar region, was movable and tender on pressure; there appeared to be a deep fissure between the tumor and the liver, no fluctuation apparent, bowel or colon not overlying the tumor. The diagnosis could not be determined, but it was presumed to be some lesion of the kidney, so it was decided to make an exploratory laparotomy.

October 19th.—I made an incision three inches long, from the edge of the tenth rib directly downward toward the border of the ilium. The tumor was exposed and found to be a very much enlarged gall-bladder with large calculi within. The viscus was very œdematous, red, and thickened. It was decided to make a cholecysto-enterostomy with my anastomosis button (No. 2). The gall-bladder was aspirated, and the running thread inserted. The running thread was then inserted into the duodenum and the intestine incised and the male half of the button inserted, the female half was then inserted in the gall-bladder through a slit made between the running thread, and the button closed. The gall-bladder measured at least 1 ctm. in thickness and was very œdematous. There was no difficulty in inserting the button. The gall-stones were allowed to remain, as I do not consider it necessary to remove them unless they are larger than the button. They will pass out after the button escapes.

October 20th.—Temperature, 101° F; pulse, 96. Vomited considerably during the night and complained of headache, which seemed to be effects of the anæsthetic. There was no pain nor abdominal tenderness.

October 21st.—At 5 P.M. yesterday the vomiting ceased, and the patient is feeling very well this morning.

October 27th.—The patient has had no unpleasant symptoms since October 20th. This morning in the stool were found two large gall-stones. The larger one weighed 117 grains (7.8 gm.); its longest diameter 1 inch, its shortest $\frac{7}{8}$ inch. The second stone 102 grains (6.8 gm.); its longest diameter $\frac{7}{8}$ inch, its shortest $\frac{3}{4}$ inch. It will be noticed that the shortest diameter of the larger stone measures exactly the same as the diameter of button used. The patient is feeling very well and is sitting up in bed. Complete primary union. Button passed eighteen days after operation.

Case III. *Cholecysto-enterostomy with Button No.* 1. —This case was referred to me by Dr. J. H. Hoelscher, who gave me the following history: Mrs. Z——, aged thirty-six, married, six children. Enjoyed perfect health until twenty-two years of age; at that time, three months after childbirth, had an attack, of short duration, of severe epigastric pain and vomiting. It was not accompanied or followed by jaundice. Ever since that attack she has had digestive disturbances, as distress following certain kinds of food, eructations of gas, constipation, loss of appetite. Four years ago she had a similar attack of pain in the epigastrium, accompanied by vomiting. From that time on the pain returned every five or six weeks, up to five months ago, when she noticed a constant aching pain and tenderness in the right hypochondriac region, that persisted until the present time. The pain and soreness were very much increased after working in a stooping posture. She has suffered much from general debility, and complains of slight and frequent chills. Throughout the entire progress of her disease jaundice was never present. The urine was tested several times for her with negative results. She does not give a distinct history of having had "hepatic colic." About three months ago she found small particles, the size of mustard-seeds, in the fæces, which someone told her were gall-stones. There is no positive evidence that she ever passed a gall-stone. Physical examination revealed a heart and lungs normal; liver not increased in size. Manipulation reveals a pear-shaped, hard tumor in the region of the gall-bladder, measuring about three inches in length, and two in width. It moves synchronously with the diaphragm in respiration. On pressure considerable pain is produced, and a slight crackling sensation is felt by the fingers.

It can be separated from the kidney, and can be moved considerably from side to side. The diagnosis of gall-stone was made by Dr. Hoelscher, and the case was referred to me for operation.

Operation, November 23, 1892, assisted by Drs. Hoelscher and Lee, in the presence of Dr. Nicholas Senn, who expressed a desire to see my method used, Dr. Dunne, of Minneapolis, and Dr. Mayo, of Rochester, Minn. The incision was made the same as in Case II.; contracted gall-bladder packed full of gall-stones slipped into the wound.

A little difficulty was experienced in drawing the duodenum forward, as some old adhesions existed. The running threads were inserted in gall-bladder and duodenum; male half of button placed in duodenum, and held by an assistant. An incision was made in the gall-bladder, which was found so full of gall-stones that half of the button could not be inserted without removing some of them. A dozen were quickly picked out with the dissecting forceps. About twice as many were allowed to remain. The female half of the button was inserted in the gall-bladder and the running thread tied. Button pressed together. Toilet of field of operation was made with dry sponge and the viscera dropped back into abdomen. Deep and superficial layer of sutures in abdominal wall. Time for entire operation, twenty-one minutes. The time for inserting the button was not taken. Patient rallied rapidly from the anæsthetic. Pulse after operation, 70. Temperature normal. Neither nausea nor vomiting.

November 25th.—Pulse, 78. Temperature, 100.5° F. Patient complains of slight pain at seat of operation. No tympanites nor abdominal tenderness.

November 28th.—Patient expresses herself as feeling very well. At no time since the operation has patient's temperature exceeded 100.5° F. She is allowed to take a quantity of liquid nourishment, but not sufficient to satisfy the appetite. I consider her now out of danger. The ease and rapidity with which this operation was performed satisfied those who witnessed it, as well as myself, that the operation of cholecysto-enterostomy by this means is relieved of many of its dangers and all of its difficulties. Dr. Hoelscher is to be congratulated on his diagnosis in this case, in the absence of so many important symptoms.

Gastro-Enterostomy.—The frequency of diseases of the pylorus and its surroundings which produce an occlusion, partial or complete, of that orifice, causes the surgeon to be frequently called upon for the relief of the unpleasant and dangerous symptoms arising therefrom. As the diseases themselves are frequently of a malignant character, or of such a nature as to be irremovable, we can only hope to relieve the patient of the unpleasant symptom of vomiting, and prevent him from dying of starvation. This operation, by which the intestine and stomach are approximated and an opening for the passage of food is made, is known as gastro-enterostomy.

The difficulty of establishing this opening by means of sutures has deterred the majority of surgeons from operating, except in desperate cases where the patient preferred death to a continuance of his miserable condition, and was occasionally accommodated with the former by the operation. The time occupied and the difficulties of the technique were so great that many of the patients on whom the operation was performed succumbed from the prolonged anæsthesia and long exposure of the abdominal contents; or, surviving these, died from a defect in the sutures or slonghing through at the line of suture. Mortality before bone-plates were used (with suture), 42.8; with bone-plates, 24.5 per cent. If the surgeon had some means by which he could safely and rapidly approximate the stomach and intestine, I am sure he would often be able to respond in the affirmative to his patient's plaintive interrogatory, "Doctor, can you not do something

for this vomiting and starvation?" When the doctor has the means of performing this operation, even as an amateur, in the short space of nine minutes, and after a little practice in as low as six minutes, as I have done on the living patient; when the technique is so simple that his patient is free from the effect of the prolonged exposure of the abdominal contents, I am sure he will undertake it with pleasure and confidence; and would have no hesitancy in applying such a simple procedure to rescue his patient from such an extremely unpleasant and dangerous condition. True, in the malignant growth the disease is not cured by gastro-enterostomy, but that most unpleasant of all symptoms, the constant vomiting, is relieved, and the patient is allowed to lead a life of comparative comfort until the end is brought on by general marasmus. The following experiments were made:

Experiment 16.—July 27, 1892. Black hound, same as in Experiment 9; weight 55 pounds. An incision in the linea alba from the xiphoid cartilage extending down three inches. Omentum torn. The under surface of the stomach was exposed and drawn into the wound with the fingers. A loop of jejunum from the neighborhood of the left kidney was also drawn into the wound. The running threads were inserted in the stomach and bowel. The incision was first made in the stomach, and male portion of the button inserted, the running thread tied and cut short. The button was now pressed together, a perfect approximation being produced. The mass dropped back into the abdominal cavity. Time, fourteen minutes. July 28th, dog appeared in perfect health; not the least unpleasant symptom; playful, and ate as usual. August 23d, dog killed; found perfect union of stomach and intestine. The tissue clasped within the button did not completely slough, and the button was held in position. The reason the tissue did not slough was on account of the thickness of the walls of the stomach. After a certain degree of atrophy had taken place pressure ceased, and there was sufficient tissue retained between the edges of the button to keep up the circulation in tissue within clasp of button. This operation was performed with the button before I had the elastic compression ring attached to it, and the fact that sloughing did not take place was what led to this modification.

Experiment 17.—July 31, 1892. Brown female dog, weight 22 pounds. Gastro-enterostomy. The duodenum was joined to the stomach near the head of the pancreas. No gastric fluid nor gases escaped during the operation. The button was inserted as above; no omental flap; two rows of sutures in the abdominal wall. The dog showed no unpleasant symptoms after the operation. Time, fourteen minutes. August 9th, killed dog; found a perfect union of duodenum and stomach; button yet in position, as shown in specimen. The dog was killed thus early to ascertain the degree of atrophy at end of ten days.

Experiment 20.—August 23, 1892. Brown female, weight 100 pounds. Gastro-enterostomy. Performed in my laboratory by Dr. Alex C. Wiener. The under surface of the stomach was exposed as above, the duodenum brought forward, the button inserted and compressed. Time, twelve minutes. The dog showed no unpleasant symptoms after the operation, eating and drinking as usual, and very playful. September 7th, fifteen days after the operation, found perfect union of stomach and bowel; button still in position; partial atrophy of tissue clasped within it.

Experiment 23.—August 30, 1892. Woolly female, weight 70 pounds. Gastro-enterostomy. Performed in my laboratory by Dr. C. Fenger. Method of operation same as above. Time, nine minutes. A new button was used in this operation, and the degree of pressure greater than in the previous ones. Dog died on the third day. It was found on post-mortem examination that the manufacturer, in his endeavor to make the button light, had made the rim of bowl at one place so thin that it had a cutting edge, and it cut completely through the wall of the stomach and bowel at the time of operation. A similar button was used in another case with the same result.

I performed the operation of gastro-enterostomy three times with the button on the human subject, and Dr. Wiener did it once. In all of the cases we got a primary adhesion. I will give a detailed report of these cases in a subsequent clinical paper on the subject, which I am preparing.

Pylorectomy.—The operation for removal of the pylorus with a portion of the stomach and duodenum. The operation was first performed by Rydyger, but Billroth and Woelfler brought it most prominently before the profession. I will not go further into the history of the operation, with which you are all familiar. In performing this operation I have deviated considerably from the beaten path, and proceeded as follows:

After drawing the pylorus into the abdominal wound, ligating the greater and lesser omenta and cutting them off, I then made a circular incision with the scissors on groove director, cutting through the muscular and serous coats of the stomach down to mucous coat, completely around the stomach where it was to be excised. I then denuded the mucous membrane of its muscular and serous coats for half an inch in the direction of the pylorus. A silk ligature was placed around the mucous coat at the line of the original incision. A large compression forceps was placed on portion of stomach to be removed. The mucous membrane was cut off half an inch below the ligature. This then presented the appearance of a rosette. A puckering stitch was run all around the edge of the mucous membrane and tied. The silk ligature was then removed. An interrupted silkworm-gut suture approximated the peritoneal and muscular coats of the stomach over the corrugated stump of the mucous membrane, completely closing the end of the stomach. The duodenum was excised an inch and a half below the pylorus, a running thread was placed in position and the button inserted. The other half of the button was inserted in the posterior wall of the stomach, two inches from line of suture, in the usual way, and the button pressed together. It was found before placing the button in the duodenum that the head of the pancreas came within an inch of the pylorus, and that the bowel had to be denuded of a portion of its peritoneum by loosening the end of the pancreas in order to allow the button to be closed. This would not occur in the human subject, as the head of the pancreas is a considerable distance from the pylorus.

The advantage of this operation over the one frequently performed—that of sewing the end of the bowel in the opening made by the excision of the stomach—is, first, that there is no dead point at the angle of suture between the stomach and bowel, which has been the cause of the greatest fatality in this operation; second, the rapid and easy closure of the mucous coat; third, the assurance that there would be sufficient opening for the easy exit of the contents of the stomach during the process of healing, thus preventing tension of the sutures at the end of the stomach; fourth, advantage over the lateral approximation operation by mixing of the food with the secretions of the liver and pancreas in about their normal way, and avoiding the danger of the great contraction that follows it; fifth, the great saving of time, the operation in the usual way occupying three and one-half to four hours, while in this method it occupies about one hour; sixth, no possibility of escape of stomach contents at time of operation; seventh, that there is but very little hemorrhage. The following experiments were performed:

Experiment 30.—September 14, 1892. Black and white dog, weight 60 pounds. Pylorectomy. Ligature of greater and lesser omenta; separated the same from the pylorus. Complete circular incision was made through serous and muscular coats of stomach down to

the mucous membrane. The mucous membrane was denuded of its serous and muscular coats for half an inch from incision in direction of pylorus. Silk ligature placed embracing entire mucous layer, incised through mucous membrane, and tied. Ligature removed. Interrupted silk sutures approximated muscular and serous coats at same time. Excision of duodenum an inch and a half below pylorus. Running thread placed in bowel, and half of button put in position. It was found that the head of the pancreas had to be torn from the attachment to the bowel in order to admit of the closing of the button. Posterior wall of stomach incised, and other half of button inserted. Button pressed together, and all dropped back into the abdomen. No omental flap. Time was saved in the manner of treating the mucous membrane of the stomach, which had not hitherto been suggested. No escape of contents into abdomen. Time, forty-four minutes. Dog killed on September 27th; a considerable quantity of sero purulent fluid in abdomen; the silk sutures at the end of the stomach had suppurated; the mucous membrane was firmly united; the bowel firmly adherent to the stomach; the button in position. On one side a small sinus, leading half an inch

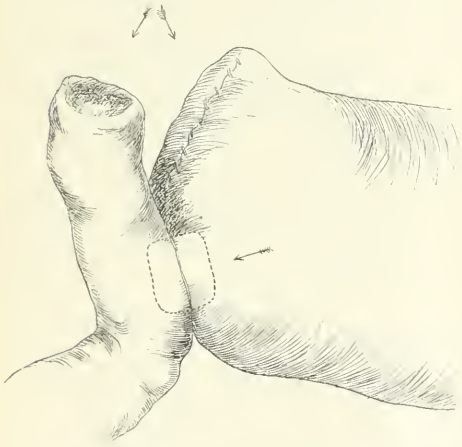

Fig. 7.—Pylorectomy. Lateral Approximation of Duodenum to Stomach.

from the edge of the bowel along the wall of the stomach was found, which had not perforated into the abdominal cavity. This sinus occurred where the end of the pancreas had been torn from the bowel.

Experiment 32.—October 2, 1892. Black dog, weight 90 pounds. Operation performed as in Experiment 30, except that the duodenum was sewed at the end with continuous silkworm-gut suture, and a lateral anastomosis made with the button between the duodenum and stomach, three inches from end of duodenum (Fig. 7). Time, sixty-two minutes. Operation made with new spring button. October 10th, the dog has been sick with the influenza from the time of the operation until October 9th, when he again began to eat. October 15th, the dog died from influenza. Autopsy showed a perfect union between stomach and bowel, with a linear cicatrix. The button had passed; the opening left was as large as the button and looked as though it had been punched out, as seen in this ideal specimen.

End-to-End Approximation of Intestine.—The many diseased conditions of the intestinal tract leading to obstruction, the many accidents resulting in strangulation and local death, the many injuries to the intestinal canal causing solution of continuity, have led to extensive study and numerous operative procedures for the purpose of restoring the bowel to its normal condition, and re-establishing the circulation of its contents. Many have been the methods that have been suggested, and still more numerous have been the modifications. This has been especially true in the last decade, and still we had not attained an ideal means of securing a perfect union. For centuries efforts had been made to unite the bowel in its most natural position, that is, end to end. More recently the tendency in experiments has been to unite it laterally. The various means hitherto used to produce apposition I will divide into two classes: first, the suture; and, second, the insertion in the bowel of a foreign body as an assistance to the suture. Of the suture I will not speak, except to call your attention to the one recently devised by Dr. M. E. Connell, of Milwaukee, which is certainly worth a trial. Foreign bodies in the shape of cylinders, both soluble and insoluble, such as the tracheæ of animals, tallow candles, sections of dried intestine, sections of elderwood, metallic rings, gelatine and rubber tubes, and very many other materials have been used. These have been tried from time to time, always in connection with the suture. Some of them have rendered good service, and still hold a respectable place as an aid to the suture in circular enterorrhaphy, as Pall's decalcified bone-tubes, Byron Robinson's rubber tube, with which he obtained good results, and still later, Jessett's ingenious device. The advantages and disadvantages of these various devices you already understand. The device which I have shown to you to-day differs from all that have been used before in the following particulars or combinations of them; first, in that it retains its position automatically when closed; second, that it produces its union independently of suture; third, that there is a perfect approximation of serous surfaces, and that that approximation must remain until a pressure atrophy takes place where the ends of the bowel are pressed together. There are precautions to be taken in putting in the running thread in the end of the bowel. If you carefully follow the lines indicated by the suture (Fig. 8), you will, 1st, prevent the eversion of the mucous membrane; and, 2d, you will produce an overlapping of both layers of the serous coat of the mesentery at point *a*, Fig. 8.

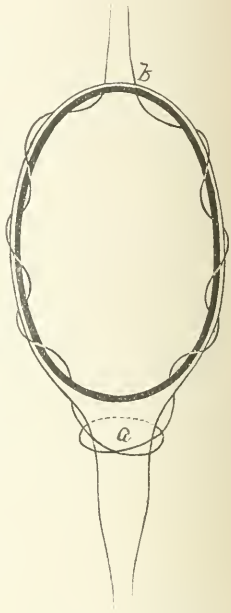

Fig. 8.—Manner of Inserting Running Thread in End of Bowel.

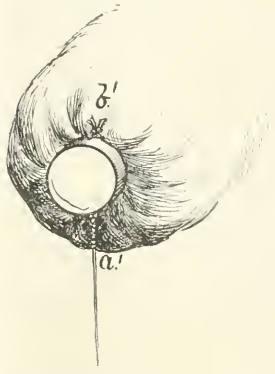

Fig. 9.—Appearance after Drawing Running Thread around Cylinder of Button.

This overlapping is produced, as you will notice in the figure, by making one top stitch at that point (*a*). This

approximation of the two peritoneal layers of the mesentery is of vital importance, as otherwise you would have the muscular layers of the bowel coming in contact between the edges of the button and get no adhesion. If the running thread is properly applied as in Fig. 8, when tied it will have the appearance of Fig. 9, and have a continuous surface of peritoneum around the entire edge of the button.

When inserting the half of the button to which the circular ring is attached, compress the ring to a level with the bowl, grasp the edge of the bowl with the forceps

Fig. 10.—Appearance of Ends of Bowel with Portions of Button Inserted Ready to Close.

and hold it compressed while you make the first half of the knot, and draw the end of the bowel close about the central cylinder; then change the forceps to the edge of the cylinder, and complete the knot. When the button was first devised it was not intended to use it for this purpose, but I find it very well adapted to intestinal approximation, as shown by the following experiments:

Experiment 12.—July 7, 1892. Brown female dog, a St. Bernard, weight 80 pounds; the same as used in Experiment 7. End-to-end approximation of ileum by

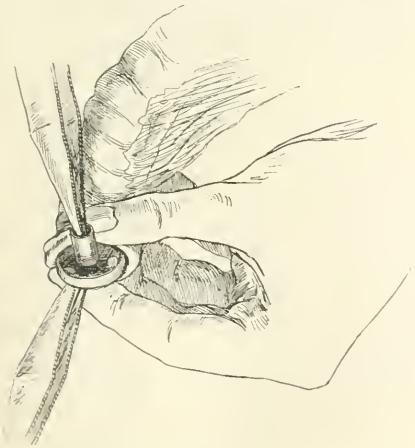

Fig. 11.—Manner of Holding Button and Bowel while Inserting Button.

means of button. The bowel was freed of its contents by gentle pressure with the fingers; it was incised; a running thread was inserted around the proximal end of the bowel, close to its edge, and the half of the button inserted (Fig. 11); the distal end was treated in like manner and the other portion of the button placed in position and the button pressed together (Fig. 12). Omental flap was placed around the point of union, and held in place by the silkworm-gut sutures. Time of operation, twelve minutes. The dog showed no unpleasant symptoms after the operation. July 27th, examined the result of this operation; while making cæcectomy on the same dog, found a perfect union between the ends of the bowel; omentum adherent all around; no adhesions between the united intestine and abdominal wall. There was no contraction of bowel at the seat of union, and it was very difficult to make out the line of approximation on the serous surface. The button had already passed. August 9th, killed dog; found the bowel as described above. There were three operations on this dog—chole-cysto-enterostomy, end-to-end approximation of the ileum, and cæcectomy, with end of small intestine approximated to end of large intestine.

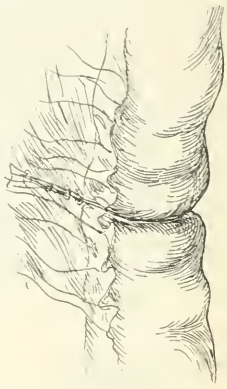

Fig. 12.—Same as Fig. 10, closed.

Experiment 11.—July 5, 1892. Black and white dog, weight 60 pounds. End to-end approximation. Omental flap. Continuous silkworm-gut suture was used in abdomen. The dog was not sick after the operation. On July 10th, five days after the operation, the dog, in licking the wound, loosened the suture and allowed the bowel to escape. He was then killed. The ends of the bowel were perfectly adherent; a plastic exudate obliterated the line of union on the peritoneal side of the bowel. The button was found in position (Fig. 13).

Experiment 14.—July 11, 1892. Spotted dog, same as in Experiment 3, of which you will hear later; weight 55 pounds. End-to-end approximation. Button No. 2 was found to be too large to be admitted into the bowel and gall-bladder button (No 1.) was substituted. This gall-

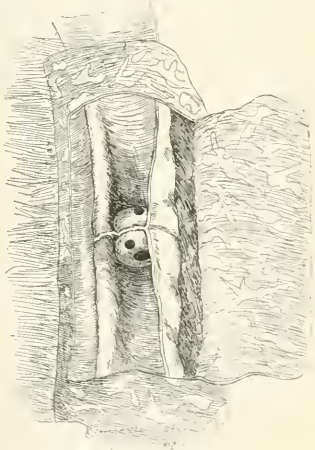

Fig. 13.—Appearance after Union and Partial Atrophy of Tissue within Clasp of Button has Taken Place.

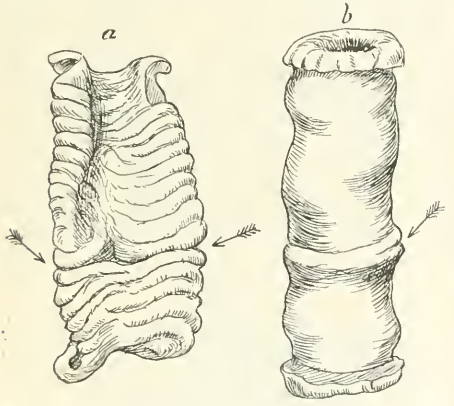
bladder button, as you see, has an opening not more than the eighth of an inch in diameter. I felt very apprehensive that this would be plugged by hair. Time, fifteen minutes. The dog was not in the least sick after the operation, and the button was passed on the sixth day. August 31st, killed dog; found a perfectly united bowel; omental flap adherent; no adhesion to abdominal wall. The union on the mucous side of the bowel was so perfect that the line could be made out only at one point (Fig. 4). No fistula, and no contraction at point of union.

Dr. Fenger was present at the autopsy and declared, "The union is perfect."

Experiment 19.—August 9, 1892. Black female dog, weight 70 pounds. End-to-end approximation after excision of six inches of bowel. Omental flap. Time, nine minutes. August 22d, dog killed; found a union around the circumference, except at one point where the mesentery joins the bowel; here there was a small sinus leading down along the mesentery. The button was still in position. Up to this time in the end-to-end approximation, and in this operation as well, no particular care was taken to see that the peritoneum of the mesentery overlapped, so as to prevent a portion of the muscular and mucous membrane being compressed between the edges of the button without having perito neum covering them to form adhesion. This accounts for the sinus which existed in this case.

Experiment 23.—September 7, 1892. Black curly dog, weight 40 pounds. End-to end approximation of ileum. Small button (No. 1). Omental flap. Time eleven minutes. September 29th, dog killed; perfect union of bowel; omentum not adherent; opening in bowel small, but of same size as button used, button had passed.



Figs. 14 and 15.—Appearance of Mucous and Serous Surfaces of Bowel after Union.

Experiment 26.—September 8, 1892. Bull-dog, weight 55 pounds. Operated on by Dr. F. S. Hartmann in my laboratory. Excision of six inches of ileum with end-to-end approximation. Button No. 1. No omental flap. Care was taken in inserting the running thread to overlap the peritoneum at the mesentery. Time, fourteen minutes. October 2d, opened dog's abdomen; found perfect union; button had passed; bowel somewhat smaller at point of union. The specimen was excised with six inches of the bowel, and another end-to-end approximation made on same dog.

Experiment 33.—October 2, 1892. Same dog as in Experiment 26. End-to-end approximation of ileum, after excising specimen from Experiment 26, along with six inches of bowel. Operated on by Dr. Hartmann. The button was inserted in the usual way. No omental flap. No scarification. Time, sixteen minutes. October 10th, the dog was playful, and ate as usual. October 12th, button was passed. There was no spring in this button. October 15th, dog killed; found perfect union; no sinus.

Experiment 28.—August 9, 1892. End-to-end approximation of ileum, performed in my laboratory by Dr. H. R. Wittwer. Same dog as in Experiment 21. Time fourteen minutes. Omental flap. September 16th, dog killed; found perfect union of bowel. The circumference of the bowel showed only partial atrophy of portion in clasp of button.

Experiment 29.—September 25th, Appleton, Wis. End-to-end approximation of jejunum, button (No. 2). Time, seven minutes. Dog killed seven days after the operation, and specimen examined by my preceptor, Dr. J. R. Reilly, of Appleton, Wis. He reported a perfect union of bowel; the atrophy was not completed. The button still in position.

Lateral Approximation or Intestinal Anastomosis.—By lateral approximation or intestinal anastomosis we understand the formation of a fistulous opening between two coils of intestine. It is performed where it is desirable to have the intestinal contents prevented from passing through a more or less constricted portion of the bowel, and where the bowel is not sufficiently constricted to cause gangrene, and it is not necessary to extirpate the constricted portion. The suggestion for such a communication originated with Maisonneuve. He was also the first to operate; both of his cases terminated fatally.

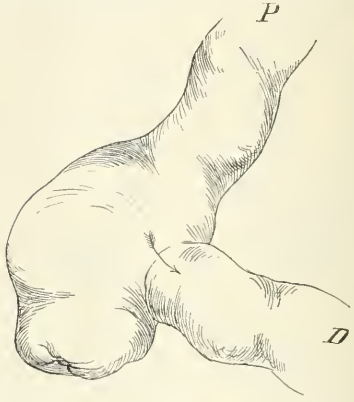


Fig. 16.—Distal End Joined to Proximal Side of Bowel after Excision (wrong way).

Fig. 17.—Proximal End Joined to Distal Side after Excision of Portion of Bowel (right way).

The operation was almost completely forgotten until 1868, when Hacken made some experiments on dogs, and recently E. Hahn, of Berlin, brought the subject again before the profession, and still later great stress was put on the operation by Dr. Senn. The great fear of the operation was the accumulation of fæces in the excluded portion of the intestine. This fear has been found to be visionary, as the experiments recently made on animals show that if the bowel is united so that its contents continue in a direct line, that is, without making a sharp curve, there would be no fear of retention or accumulation, providing the anastomotic opening is sufficiently large. The operation was first performed with sutures. Dr. M. E. Connell, Superintendent of the Milwaukee Hospital, suggested the use of perforated plates (see Senn's "Experimental Surgery"), which were subsequently used by Dr. Senn in his excellent experiments. The first plates used were made of wood, gutta-percha, leather, and lead. Subsequently the disks were made of absorbable material, as decalcified bone. Now we have many modi-

fications of the method, using, in place of the bone-plates, segmented wood, coil of heavy catgut, etc. It was hoped from the results of the early experiments that the operation upon man of lateral approximation would be fraught with much less danger than the end-to-end. But the degree of contraction following lateral anastomosis, and the invagination of the distal end of the bowel into its lumen have increased the danger until it is equal to that of the end-to-end approximation. I have used the buttons for the lateral as well as the end-to-side approximation. The following are the experiments:

Experiment 5.—June 24, 1892. Lateral anastomosis of the jejunum with button. Operation very easily executed. Time, seven minutes. Dog had no unpleasant symptoms. Dog killed July 26th; found a perfect lateral union; opening as large as button. No accumulation of fæces in loop, but considerable atrophy. Button had passed.

Experiment 8.—June 14, 1892. Coach-dog, female, weight 80 pounds. Lateral anastomosis of ileum; very easily performed; no escape of gas or fluids; perfect approximation. Time, sixteen minutes. The dog showed no unpleasant symptoms. July 1st, killed dog with chloroform. Found perfect union of bowel; moderately large opening; loop very much contracted; no accumulation of fæces in loop; no adhesion to abdominal wall.

Experiment 9.—June 24, 1892. Black dog, weight 55 pounds, same as used in Experiment 5. Excision of two inches of jejunum. Both ends of bowel sewed with silkworm-gut sutures. Lateral approximation performed. With this experiment the direction of the bowel was purposely reversed, to see what effect it would have on the adhesion. The contents of the canal, after passing through the fistulous opening, had to move in a direction opposite to its previous course before passing through the fistula. Time for suturing ends of bowels, fourteen minutes; lateral approximation with button, eleven minutes. Total time of operation, twenty-five minutes. No omental flap. Scarification of the serous surface before approximation. The dog did not appear sick after the operation. August 23d, dog killed. Found perfect union at point of approximation. This is the most trying test that a mechanical device for producing adhesions can be subjected to. Found small invagination of upper portion of distal end; lower end of proximal portion of bowel very much dilated, as was anticipated; mucous membrane inflamed and one spot ulcerated. Considerable hair had accumulated in pouch. This is in accordance with the experiments performed by the other investigators where the current of the intestinal canal was made to reverse its direction at any point.

Experiment 25.—September 8, 1892. Resection of six inches of jejunum. Approximation of the end of distal portion to the side of proximal portion of the bowel, wrong way. This is also a very severe test on the adhesion. Approximation to side one and one-half inch from end. End of proximal portion sutured with silkworm-gut. Time, eighteen minutes. September 22d, dog died, as predicted. Proximal portion of the bowel very much distended (Fig. 16); large accumulation of hair and fæces, as anticipated; button still in position; bowel perfectly adherent at point of apposition.

Experiment 27.—September 9, 1892. Black and white dog, weight 45 pounds. Approximation of the proximal end to side of distal portion of bowel, right way, after resection of six inches of jejunum (Fig. 17). Here it was necessary to determine which was proximal and which was distal end. This is done as follows: A loop of bowel is held between the fingers and parallel to the axis of the body; the finger is slipped along down the side of the mesentery; if it goes to the same side as started the portion toward the head is proximal, if it goes to the opposite side the portion toward the head is distal. End of bowel sewed with silkworm-gut suture. Time, nineteen minutes. Dog killed October 2d. Large piece of bone found in opening of button, completely closing it. Pressure atrophy of one-half of the circumference of the bowel that was clasped within the button had taken place, so that the fluid passed on in the alimentary canal on the side of the button in place of through the centre. There was a perfect union of bowel at point of approximation, as you will see in specimen. The line of union on the mucous side could scarcely be discerned. This specimen shows more perfectly than any other the various stages of the process of pressure atrophy.

Excision of Cæcum with Ileo-Colostomy.—This operation may be necessary, and should be successful in certain cases of carcinoma of the cæcum. The removal of this portion of the intestine has so far been followed by unfavorable results, but our advanced knowledge of intestinal surgery should make it a comparatively favorable operation. The best incision for this operation on the human subject should be from the middle of Poupart's ligament down over the tumor through the linea semilunaris. Length of incision must be governed by the size of the tumor. The cæcum is drawn out through the opening, its mesentery ligated, the required portion excised, the end sutured, the ileum cut off, and the end of the ileum approximated to the side of the colon. Experiment—end of small to end of large intestine.

Experiment 15.—July 27, 1892. Brown female dog,

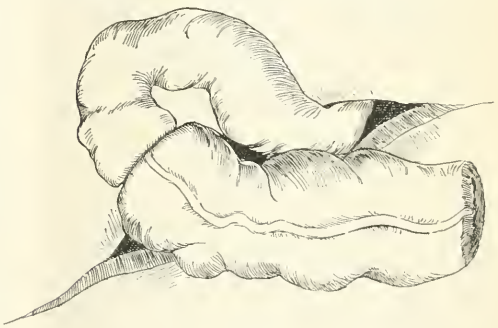

FIG. 18.—Result after Joining End of Small to End of Large Intestine (Excision of Cæcum).

same as used in Experiments 7 and 12. Excision of cæcum; running thread put around the entire circumference of the colon, and the edge drawn within the clasp of button (No. 3). A similar thread put in the end of ileum and tied; button pressed together. This approximated the end of the small to the end of the large intestine. Time, thirty-one minutes. July 28th, dog not in very good condition, refusing to eat or drink. July 30th, dog still sick and declining to eat. From that time on did very well. August 9th, killed dog. Found a perfect union of the end of the small to the end of the large intestine; button had passed; omental flap adherent; opening of same calibre as that of small intestine (Fig. 18). See specimen.

Experiment 31.—August 14, 1892. Black, curly, female dog, weight 125 pounds. Ileo-colostomy. Ileum cut off at ileo-cæcal valve; opening in cæcum sewed with continuous silkworm-gut, Lembert suture. Half of button pressed in end of ileum and the other half inserted in an opening made in colon, three inches below the ileo-cæcal valve, and button joined. Omental flap. Time, sixteen minutes. In closing the abdomen the large omentum was included in the peritoneal suture. September 20th, dog had a miscarriage. September 29th, dog died. Autopsy showed the cause of death to be a volvulus around the omentum where it was adherent to the cicatrix in the abdominal wall. Perfect union between ileum and colon (Fig. 19); button in position; atrophy over half of its circumference; no obstruction at the seat of button; no peritonitis. This is a very

instructive case, as it shows one of the complications that may arise from including the omentum with the peritoneal suture of the abdominal wall, so frequently advised and practised by many operators at the present time.

Besides the above cases three dogs were lost with the anæsthetic. One dog was sick when brought from the pound; he was operated on the following morning, and died twelve hours after, never being able to stand from the time he was taken from the table. The operation lasted only eighteen minutes, and had nothing to do with the cause of his death. In every experiment we obtained union at the seat of approximation. This is one of the most important points brought out by the button, for it

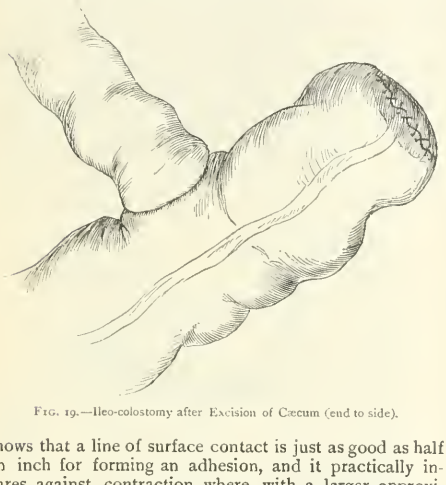

Fig. 19.—Ileo-colostomy after Excision of Cæcum (end to side).

shows that a line of surface contact is just as good as half an inch for forming an adhesion, and it practically insures against contraction where, with a larger approximation surface, contraction would certainly follow. I desire to express my thanks for, and appreciation of, the valuable services rendered me in my experiments and operations by Drs. E. W. Lee, F. S. Hartmann, and H. R. Wittwer, and by Dr. J. H. Hoelscher in placing material at my disposal; my obligations to Dr. Wiener for using my method at an early date and to Dr. E. A. Matthæi for the drawings.

A Quart a Day for Drinking and Washing.—The victualling scale of allowance of fresh water upon ships, more especially on board British sailing vessels, should obviously, according to Dr. Collingridge, be considerably increased. As it at present stands, an English contemporary asserts, it amounts only to three quarts a day for each man, of which two quarts are handed over to the cook for tea, coffee, soup, etc., leaving one quart only for drinking and washing purposes.

QUININE IN CHOLERA.

Second Paper.

By ERSKINE B. FULLERTON, A.M., M.D.,

Professor of Materia Medica and Therapeutics, Starling Medical College, Columbus, O.

A former communication,[1] giving my own experience during the cholera epidemic of 1873, contained a comparison between quinine and mercuric chloride, as to amounts necessary to inhibit the growth of the cholera spirillum. Since then, in a ten-minute discussion of the "Treatment of Cholera," before the Medical Section of the Mississippi Valley Medical Association, the following more complete list with comparative amounts was given. The list of inhibitory amounts is from that of Professor Koch, made public in 1884, with the exception of tannic acid, from Cantani, and salol, from Löwenthal, the estimate for the latter being based upon his lowest amount for sterilizing or (as it did not always sterilize) inhibiting the growth of the germ. One grain of quinine, which inhibits in strength of 1 to 5,000; is used as the standard of comparison, and results are given in round numbers, as inhibitory amounts doubtless were.

Koch's List.

Alcohol, 10 to 100	Quinine.	1 grain	=	1 fluid ounce.
Alum, 1 to 100	"	1 "	=	50 grains.
Camphor, 1 to 300	"	1 "	=	$16\frac{2}{3}$ grains.
Ac. carbolic, 1 to 400	"	1 "	=	$12\frac{1}{2}$ grains.
Oil peppermint, 1 to 2,000	"	1 "	=	$2\frac{1}{2}$ ℥.
Sulph. copper, 1 to 2,500	"	1 "	=	2 grains.
Salol, 1 to 100	"	1 "	=	50 grains.
Tannin, 1 to 200	"	1 "	=	25 grains.
Cor. sublimate, 1 to 100,000	"	1 "	=	$\frac{1}{20}$ grain.

Forty grains of quinine is not a very formidable amount to be given in the course of a day, or, for that matter, in a few hours, if occasion required, but the relative quantities of these other drugs seem very large; $2\frac{1}{2}$ quarts of whiskey, brandy, gin, or rum; $666\frac{2}{3}$ grains of camphor, 500 grains of carbolic acid, 100 minims of oil of peppermint, 80 grains of blue vitriol, 2,000 grains of salol, 1,000 grains of tannin, 2 grains of mercuric chloride.

Calomel having little if any effect upon the germ, and opium being necessary to control peristalsis in the guinea-pig, before he can be made to take the disease, the logic of the situation seems to point plainly to quinine as the least harmful, and therefore the most efficient remedy, even in choleraic diarrhœa, or in moderately severe attacks of cholera, where the treatment may be carried through several days. How would it be in "foudroyant," "fulminant," or "explosive" cases, where if anything is to be done it must be done quickly, and enough of the remedy given in the course of two or three hours to arrest multiplication of the germ throughout the whole intestinal tract? In full view of the modern theory that such cases may be the result of toxic absorption rather than the presence of the spirilla in overwhelming numbers in the intestines, it seems but reasonable that by inhibiting the growth of the germ one may at least limit the further production of the toxines. Whatever other treatment may be used, in foudroyant arsenicism we would hardly be justified in withholding the proper antidotes for arsenical poisoning. Even in septicæmia quinine as yet holds the field against all-comers.

The latest estimate from Hamburg (September 8, 1892), places the death-rate at forty-four per cent., and the probability is, that when the full count is in, the loss will closely approximate the old one of about fifty per cent. So far as heard from, the good results to above date seem attributable to hypodermoclysis. The word comes from Paris that Beta naphthol has failed. Salol has failed, and the reason of its failure is apparent when we know that Löwenthal's 20 grammes (300 grains) daily, which according to his theory should set free in the duodenum the large amount of 120 grains of carbolic acid, only equals, after all, so far as inhibitory effect is obtained, 6

[1] Medical Record, October 1, 1892.

grains, or, estimating the carbolic acid alone, less than 10 grains of quinine, the 45 grains of Gonzales, of Salvador, about 1 grain, and the 120 grains daily of Nicholson, of Patna, India, less than 3 grains of quinine. Tannin enteroclysis has failed in spite of Dr. Shakespeare's expressed opinion that "with such an instrument not only the whole length of the colon can be filled with the desired fluid, but also not infrequently a quantity can be made to pass the ileo-cæcal valve into the small intestine." That is to say, a small amount of the remedy be placed just where it is most needed. Quinine failed by the hypodermic method of administration in 1873 and 1884. The germ being inside the intestine, and not in the circulation, and the affinity of the remedy for the kidneys, and not for the bowel, this method of using it would seem as irrational as the administration of sulphites or sulphur by the mouth in the treatment of cycosis, chloasma, or scabies. That by this method of using quinine the damaged kidneys might be impeded in their function, and if there be aught in the old uræmic theory of blood-poisoning in cholera, this undesired event, insured by the further retention of urea and uric acid to the extent of about forty per cent. where complete suppression of urine has not occurred, is easy to understand.

To reach the seat of the disease the remedy must be given by the mouth, and the only noteworthy objection to this use of quinine is the old idea that quinine, under certain conditions, is very irritating to the stomach. In the disturbed stomach of remittent fever we do not always regard this symptom, and it was my own experience in 1873 that this remedy seemed a very good anti-emetic in cholera. In the whole history of that epidemic (Woodworth, McClellan, *et al.*) there is, if I mistake not, but once mention of its having been vomited, and in that case it was given in conjunction with capsicum, not repeated, the patient put upon other treatment and dying thereafter.

Has quinine by the mouth given good results in cholera? I think it has.

Botkin, in 1871, in the *Wiener Med. Presse*, reports a loss of but 17.3 per cent. under the use of quinine. He gave 5-grain doses three or four (sic) times daily, and when vomited resorted to hypodermic injections of 8 grains frequently during the day. If the latter dose, dissolved as it was, had been given by the mouth, and in case of vomiting thereafter had been repeated until about 30 grains had been retained, and continued in small doses so long as symptoms seemed to require it, there might have been a better result even than the above very favorable showing.

Owing to a persistent denial on the part of the authorities at New Orleans that cholera had been imported there in 1873, the profession in the Mississippi Valley (to which this invasion was limited) was left to make its own diagnosis as to the nature of the disease then prevailing. As late as September of that year, or seven months after the epidemic broke out in that city, the New Orleans *Medical and Surgical Journal* discredited the importation of the disease, and the editor admits having considered it at first catarrhal in character. Of the eighty cases first reported, forty-six went on record as cholera morbus, "cholera Asiatica appearing infrequently." The idea of a cholera Mississippiensis was very prevalent during the early history of the epidemic in the lower valley, and throughout its entire history many physicians held to the belief of its malarial origin. This is especially noticeable in Tennessee and Kentucky. Quinine is frequently mentioned in treatment, but too often it is the last remedy of the list, and in but few cases, comparatively, is the size of the dose, the method employed, or the frequency of its administration noted. Good results occasionally obtain after 5-grain doses by the mouth, and several recoveries after rectal injections of the drug in varying quantities. One writer states that the disease was very fatal unless the patient was seen early and large doses of quinine given, and two instances are recorded where the patients recovered after the large amounts of half an ounce in the one case, and two-thirds ounce in the other, had been taken. On such data, however, it is impossible to arrive at any satisfactory conclusion other than that, generally, the results seem favorable.

There is one exception to this rule, and the treatment and its results are so very remarkable as to be nearly unique in the history of medicine, and on so large a scale as almost to force conviction. As recorded in the volume entitled "The Cholera Epidemic of 1873 in the United States," the facts are as follows:

About May 1, 1873, the authorities in control of the Tennessee penitentiary at Nashville, Tenn., received notice that a malignant disease had broken out among two camps of convicts at work along the line of the Memphis & Paducah Railroad. As to how fatal it was there are several conflicting statements. Fortunately we have, on page 137 of the above-mentioned volume, the report of the chief engineer of the road, Mr. J. L. Meigs, which gives the whole number sick of the disease from May 1st to 13th as forty, and the number of deaths twenty four, a fatality of sixty per cent. On the 12th of that month convicts to the number of seventy-five were sent back to the penitentiary at Nashville, purging and vomiting. On arrival about one-half only of this number could be accommodated in the hospital, the remainder being shut up in cells, usually two in a cell having a capacity of two hundred and fifty cubic feet of air, ventilation being through a grating, fourteen inches square, in the cell door, with the bucket that received the choleraic discharges inside the cell.

The diagnosis "scorbuto-malaria" was made by the physician of the penitentiary, and the sick put upon a diet of fresh vegetables and saurkraut, with "tincture of iron *and quinine freely given*, chlorate of potash being used as an adjuvant." The day after the arrival one man died, this man on reaching the penitentiary "being in so much better condition than the others" that he was not admitted to the hospital, but sent to his cell. A letter recently received from Dr. George P. Henry, the physician, states that this patient had no medical treatment whatever. "The remainder recovered rapidly, and in a few weeks most of them were at work." In the above-mentioned letter Dr. Henry further states that to these seventy-four cases "I gave quinine by the mouth altogether," "freely and at short intervals at first," and that "the cases were usually under control in an hour or two after the administration of perhaps 20 or 30 grains of quinine," "that finding its potency for good I kept it up," using it later on "both by the mouth and hypodermically." Dr. W. M. Wright, at that time Superintendent of the penitentiary, in a letter recently received, states: "I think that 20 grains of quinine were given in about four hours."

From May 12th to June 8th there was an average of fifty-seven cases daily under treatment in hospital and in cells. At this last date there was an "explosion" of the disease in the city of Nashville (brought there by these same convicts), and "the fact was recognized that cholera was epidemic within the penitentiary walls." The dietary was changed in conformity to the corrected diagnosis, and during that day and the night following there were three deaths of prisoners from the disease.

On June 9, 1873, Dr. Thomas Menees, a prominent practitioner and teacher of medicine in the city of Nashville, was called in counsel, and the treatment thereafter was as follows: Calomel and opium in small doses frequently repeated, "quinine freely given either by the mouth or hypodermically." In a meeting of the physicians of Nashville, held December 16, 1874 (1873?), Dr. Henry further states, "after June 8th we treated the patients with quinine, calomel, and opium." "I called it malaria." Dr. Menees, at the same meeting, said, "we also used quinine freely," and he places the whole number treated at between four and five hundred, "prisoners and attachés." In the letter from Dr. Henry above re-

ferred to, he places the number severe enough to be called cholera at three hundred and fifty, the rest choleraic diarrhœa. Dr. Menees states that "from the 9th day of June to the 12th day of July there were twelve deaths. There were some that had chronic diseases, and when they were attacked they would die." It will be seen by the above that there were fifteen deaths after the idea that the disease was malaria was given up and the proper diagnosis of cholera made, but only one death prior to this. There are three of these cases in which it is very doubtful that they had any quinine, or if so, whether it was given in sufficient doses in the light of modern discoveries to inhibit the growth of the germ. Dr. Henry writes he cannot remember whether the three dying on June 8th had quinine or not. It will be recalled that on that date the diagnosis of cholera was made. Counting these, however, and allowing nothing for those already enfeebled by "chronic diseases," and taking the lowest figure (350) as the number of cholera patients, and the result is a death-rate of less than 4⅓ per cent. Under similar circumstances, only that the hospital accommodations were sufficient for all, the dietary arranged with reference to cholera and not to scurvy, and only a few of the diarrhœa cases given quinine in tonic doses, the death-rate in the Ohio penitentiary in this city was over seventy-five per cent.

That the disease was Asiatic cholera, which obtained access to the Mississippi Valley through the ricketty States rights' quarantine at New Orleans, is no longer a debatable question. The death-rate of fifty-two per cent. for the epidemic would alone show this. That it was of no mild type in the Tennessee penitentiary is attested by the fact that there was sixty per cent. of loss before the sick were ordered in, and furthermore, that there were one thousand deaths in the city of Nashville during the epidemic—a mortality of one in thirty of the population of the city at that time. That other remedies than quinine were used is true. Tincture of iron, chlorate of potash, "calomel and opium in small doses," camphor, "calomel inserted dry under the skin," blisters, and quinine hypodermically; but all these had been tried elsewhere and found wanting. Reasoning by exclusion the treatment other than quinine is certainly insufficient to account for the results.

To control so fatal a malady the amounts of quinine above indicated seem small, but are quite enough in view of modern developments to effect the wonderful results if continued for several days in sufficient doses to maintain the effect once gained. In my own cases fifteen grains given in the course of two hours always checked the symptoms, and three to five grains given at two hours' intervals thereafter were usually sufficient to keep the symptoms under control. For how long a period this treatment was persisted in I cannot now recall, doubtless in most of the cases for several days, as there were but two instances[1] in my own practice in which the disease tended to return. In another case in which I was consulted the patient got fourteen grains during a forenoon, with the result of checking the disease for a period of forty-eight hours. At the end of that time the symptoms returned, the patient dying in a few hours without quinine. According to the Marseilles experimenters the germ was rarely found in the discharges after four days, and never after ten days' time. The growth of the germ in the last-named case was certainly not inhibited for a sufficient length of time, and in my own cases I suspect that it was a resultant non-specific enteritis that I had to deal with.

Fifteen grains of quinine are sufficient to inhibit growth of germ in about five quarts of fluid, in case test-tube experiments hold good on so large a scale. With the rapid peristalsis of cholera, and the very small quantity of the remedy that would be lost through absorption, the currents being into and through the bowel, it is quite reasonable to suppose that even in the intestinal tube these experiments would hold good, and the quinine, instead of being absorbed, as it usually is, by the stomach, pass onward into the intestine where it is needed. As to coincident treatment I shall not venture to make suggestions. The symptoms calling for hypodermoclysis, for small hypodermic injections of morphine, for small doses of calomel, for doses large or small of bismuth or other astringents, or alteratives in the treatment of the ensuing enteritis, are sufficiently obvious.

The statement is made above that the results in the Tennessee penitentiary are nearly unique. They would have been quite so had it not been for the Naples treatment by camphor. According to Dr. Rubini there was no death among 592 patients treated with an alcoholic solution of camphor in such manner that the patient received in mild cases about thirteen grains, and in severe 66 grains of the drug in the course of one hour. The latter is a convulsant dose equivalent to 4 grains of quinine. Tested afterward in the Whitechapel Workhouse, England, there were 9 deaths out of 15 cases of the disease.

[1] In the article in MEDICAL RECORD for October 1st, but one recurrent case is mentioned. Since then, having had access to a partial report of cases made soon after the epidemic in Cincinnati Clinic, November, 1873, the other case is recalled to memory.

Progress of Medical Science.

The White Corpuscles as Protectors of the Blood.—Dr. Werigo, when examining under the microscope the blood of a rabbit which had received, some minutes before, an injection of a culture of B. prodigiosus in the auricular vein, was surprised to find the blood almost destitute of leucocytes. He repeated the experiment, with the same result, and became convinced that the phenomenon was constant. In order to prove this, he made a series of experiments, in which he injected cultures of different microbes into the blood, counting the leucocytes before and afterward. The main fact brought forward receives the following explanation: The leucocytes disappear from the blood under the above-named circumstances, because, when they have engulfed the microbes injected (which they speedily do), they are arrested in the organs, especially in the liver, where they pass on the ingested material to the endothelial cells of the organ. The rapidity with which the microbes become enclosed in the leucocytes is most astonishing—it is far greater than we have been accustomed to suppose. It is not the leucocytes alone, however, which undertake the clearance of the microbes from the blood, for the cells of the spleen pulp, and also the endothelial cells of the liver, take on direct phagocytic functions. The author's researches also lead him to consider that the first event after the injection of any microbes, of whatever virulence, is their inclusion in cells.—*The British Medical Journal.*

Cancer and Fibroids of the Uterus.—Dr. Ehrendorfer has studied this subject and gives the following conclusions: 1. The association of cancer and fibro-myoma of the corpus uteri is less rare than has been heretofore supposed, and its clinical importance should be recognized. 2. In every case of hystero-myomectomy, before treating the stump, the specimen should be examined to see if the endometrium has undergone cancerous degeneration. 3. If cancer is found in addition to the fibro-myoma, or even if the former is suspected, complete extirpation should be practised. 4. No method of treating the stump after hystero-myomectomy can promise entire immunity from recurrence under these circumstances. 5. If in a case of fibroid uterus there is a watery, sanguineous discharge, accompanied with severe colicky pains, the development of malignant degeneration of the corporeal endometrium should at once be suspected and a radical operation should be performed.—*Archiv für Gynäkologie.*

Spontaneous Reduction of Intussusception in an Infant.—An instructive case of this kind has been observed by Dr. Shewen, who gives the following account of it in

the *Australasian Medical Gazette*: A fine, healthy child, but habitually constipated, had, up to July 6th, been fed on the breast and condensed milk. During the three following days its diet was altered to breast-milk and Nestlé's food, and the bowels became so much constipated that the mother had to use a finger of soap to bring on a movement. On the following day the bowels were moved once naturally, and the child seemed perfectly well. On Monday, the 11th, the child had four motions without any pain or trouble, and went to bed seemingly as well as ever. During the night, however, he was restless, and retched twice toward morning, getting collapsed and cold afterward. Dr. Kearney was sent for. Before the doctor's arrival the child had a large light-colored stool with the faintest tinge of blood about it. The little fellow was then cold and collapsed; temperature subnormal; countenance pinched and anxious, and he was vomiting small quanties of bilious fluid. High up in the left hypochondriac region an elongated mass, about an inch in diameter and about three inches long, could be felt and manipulated without causing the child any distress. This was the intussuscepted bowel. After some severe symptoms the child eventually recovered under simple treatment. This case is interesting as showing what an amount of constitutional disturbance an intussusception, which has only been in existence for twenty-four hours, and which has returned of its own accord, will cause. The child's condition was for many hours such as to cause one the greatest anxiety. Mr. Jonathan Hutchinson recommends strongly the trial of manipulation of the abdomen and the forcible jerking of the body to and fro, previous to an abdominal section, in all such cases.

Appearance of the Eyes in Disease.—The eyes are congested in variola, scarlet fever, rubeola, yellow fever, typhus fever, meningitis. They are projecting in asphyxia, hydrocephalus, hydrophobia, exophthalmic goitre, and sometimes in functional heart disease. They are sunken in collapse, cholera, and hectic. They are staring in convulsions, apoplexy, catalepsy, meningitis, and dementia. They are rolling in epilepsy, and tuberculous meningitis. They are photophobic in hysteria, meningitis, and cephalalgia. The pupils are dilated in syncope, hysteria, collapse, asphyxia, epilepsy, drowning, uræmia, coma; generally in phthisis; poisoning by belladonna, atropia, fungi, and many vegetable irritants and narcotics. They are contracted in concussion, sunstroke, typhus fever, hemorrhage of the pons; in poisoning by opium, morphine, prussic acid, calabar bean, ergot of rye, and pilocarpine. At first contracted and afterward dilated in compression of the brain, in poisoning by alcohol, ether, and chloroform. At first dilated and afterward contracted in severe apoplexy. They are unequal in paralysis, compression of the brain, and posterior spinal sclerosis. They are frequently oscillating in epilepsy, typhus, and spinal sclerosis. In diseases of the eyes external signs facilitate diagnosis. Congested in conjunctivitis, trachoma, and ophthalmia. Dilated in mydriasis, glaucoma, and amaurosis. Contracted in myosis, retinitis, and iritis. Photophobic in strumous ophthalmia, amaurosis, iritis, sclerotitis, choroiditis, and retinitis.—*Times and Register*.

The Importance of Attitude in the Auscultation of Children.—Dr. Azoulay, of Paris, says that the difficulty often experienced in analyzing and localizing abnormal heart-sounds in the very young is known to most of us. The reason is that in the child the following elements come into play—viz., great rapidity of heart beats, the complicated character of the bruits and their vagueness. In such cases the puzzled practitioner contents himself with the hypothetical diagnosis of peri- and endo-carditis. Dr. Azoulay states that he has devised a means of rendering the problem much easier of solution. Dr. Jules Simon and himself have applied the method at the Paris Children's Hospital, and have thus been enabled to localize the extra- and intra-cardiac abnormal sounds. Dr. Azoulay places his little patients in the following attitude: trunk horizontal, dorsal position, arms raised vertically, lower limbs completely flexed, head raised. In this position of the body the normal sounds are considerably reinforced, while the beats are slowed; consequently the abnormal sounds are intensified and better localized. The assumption by the patient of the above position notably increases the pericardial friction-sound. The utility of variations of attitude is great in examinations for life insurance and in the examination of recruits. If a person supposed to be in good health experiences, when lying down, dyspnœa and arythmia, and if the heart-beats are not slowed—all of which symptoms are absent in the upright attitude—a lesion of the myocardium may be diagnosed, and a fatal issue from asystole at a date more or less remote, according to the intensity of the above symptoms, expected.—*The Lancet*.

Resection of the Liver for Hepatic Tumors.—Dr. W. W. Keen gives the results of an analysis of twenty cases of liver resection. The ages of these cases varied from twenty-one to fifty-eight years. Sixteen cases occurred in females, which the author thinks may be due to tight-lacing. The tumors and portions of liver removed have varied in size from a small nut up to three fists. Of the twenty cases, nearly all were incorrectly diagnosed; some were thought to be floating kidney, others tumors of the pancreas. The tumors were echinococcus and hydatid cysts, cancer, syphilis, sarcoma, and adenoma. Dr. Keen thinks that, judging by experiments on animals, a large portion of the liver can be removed without much danger and without interfering with its function. Ponfick found that three-fourths of the liver could be removed, although prostration was very severe at first. The escape of bile into the peritoneal cavity is generally of no consequence. In preventing hemorrhage the base of the tumor should be severed by repeated small touches of the cautery point, the large vessels being all ligated. In the majority of cases the stump was returned into the abdominal cavity; in six cases, however, it was sutured in the abdominal wound. Of the twenty cases, seventeen recovered, two died, and in one the result is unknown. The mortality thus far has been about ten per cent.—*Boston Medical and Surgical Journal*.

The Urine in Phthisis.—Dr. W. H. White has made some observations on this subject (*The British Medical Journal*). In 7 out of 9 urines examined the urine remained acid a very long time. In 182 specimens examined only 36 remained acid less than five days, and 4 remained acid for over one hundred days. All the urines were left at the temperature of the ward and freely exposed to the air at first. The sediment which formed in the acid urines consisted of amorphous urates and abundance of uric acid crystals. If it had remained acid some time abundance of yeast-like organisms could be found in it, but very few bacilli. The change is, therefore, in many respects the same as that described as acid fermentation. Most urines developed a peculiar smell, not unlike that detected in sewage-purification works. Many of the acid urines became darker and darker, becoming eventually black when seen in bulk, though only dark-brown when in thin layers. This change usually took a month or more; once black, the urine remained so, even if kept for nearly a year. The cause of the darkening is obscure; it is not, however, due to pyrocatechin. These peculiarities could not be connected with any symptom observed during life or with any post-mortem change. None of the patients who died had any local disease of the genito-urinary tract. The condition of the urine was not related to any particular drug or diet. It seems that these peculiarities of the urine are due to the excretion of some of the direct or indirect products of the action of the tubercle bacilli.

The Employment of Married Women in Factories.—That the employment of married women in factories is likely to conduce to a high infant death-rate will readily

be admitted, but perhaps we were hardly prepared to find that the injurious influence of such employment should be so great as it would appear to be from the statistics for Staffordshire, which formed the basis of a paper read by Dr. Reid at the Public Medicine Section at Nottingham. In the compilation of the figures, which had reference to a population of upward of 500,000, and extended over a period of ten years, every care seems to have been taken to exclude fallacy; and therefore, so far as Staffordshire is concerned, the case appears to have been proved. It would seem that the conditions of trade in Staffordshire enable a line to be drawn between towns corresponding in every respect as regards general influences that affect injuriously the lives of children, but differing essentially in one feature, namely, the relative proportion of married women engaged in work; and to this cause alone an increase of twenty-eight per cent. in an already high infant mortality is to be attributed. If the figures for the country generally bear any resemblance to those for Staffordshire, a very serious case is made out, and it clearly becomes a question whether legislative interference is not called for. Dr. Reid gives similar figures for towns throughout England, so far as the Registrar-General's returns permit of their being worked out.—*British Medical Journal.*

Indications for the Use of Cimicifuga.—According to Dr. Reed, ten to thirty drops of the fluid extract after meals are used to cure seminal emissions. This has rarely failed in his experience. Half a grain to a grain of the resinoid, cimicifugin, twice a day, has occasionally been found useful in conditions of nervous depression, hysteria, and incipient melancholia. Five to twenty drops of the tincture, several times a day, have proved very helpful in scanty menses, especially in maiden ladies; but if repeated, as often as every three hours even, are likely to cause severe headache. This untoward effect he has never seen from the largest doses, such as half a drachm or a drachm of the fluid extract three times a day. Very small doses, as one-quarter of a drop up to one drop of the ordinary tincture, repeated every one or two hours, will often promptly relieve a frontal headache due to mental fatigue, or any kind of a headache resulting from pelvic congestion at the menstrual period in women. The same doses are often efficient in preventing abortion when threatened from weakness or passive congestion of the uterus, or from habit at a certain stage of pregnancy. Two or three drops of the tinctures of cimicifuga and gelsemium—sometimes one drop of each—every hour or two, are among the most certain means of bringing on the menstrual flow when delayed by passive congestion, cold, grief, or other similar cause, and acts similarly with the lochial discharge after parturition. Dragging pelvic pains arising from the same causes may be relieved by the same combination.—*American Therapeutist.*

Extirpation of Cancerous Uterus in the Sixth Month of Pregnancy.—Dr. Stocker reports the case of a woman, aged thirty-six years, who had had eight children, the last some three and a half years previously. The woman again became pregnant, but soon hemorrhage and offensive discharge set in. Changes in the cervix uteri became evident. Finally, the existence of carcinoma became indubitable, and it was decided to remove the entire uterus. The operation was performed in about the sixth month of pregnancy. The body of the uterus was removed through an opening in the abdomen; the cervix through the vagina. The fœtus died during the operation. Little blood was lost. The patient was dismissed from the hospital on the twenty-eighth day after the operation.—*Centralblatt für Gynäkologie.*

Toxicity of the Serum in Cases of Eclampsia.—Puerperal convulsions are now generally regarded as the outcome of auto-intoxication. Bouchard has demonstrated the lessened toxicity of the urine passed, often only in diminished quantity, by such patients. It occurred to Dr. Chambrelent, of Paris, to supplement these observations of Bouchard by examining the serum of the blood drawn during the attacks (*The Lancet*). Taking as a basis the fact already established by Rummo, that about five ounces of healthy human serum is the quantity to kill two pounds of rabbit, he found that this degree of toxicity was greatly exceeded when eclamptic serum was employed, and that there was a constant relation between the poisonous properties of the serum and the gravity of the case. Six patients were the subjects of the above experiments at the Obstetric Clinic of the Paris Faculty.

Tetanus Treated by Cold Baths.—Dr. Rivière has observed two cases of tetanus with high temperature treated with cold baths. In each case chloral and opium had failed to give relief, and as the temperature was high it occurred to the author to try the effect of immersing the patients in cold baths. This was done with marked success, there being in one case no recurrence of trismus or rise of temperature, and convalescence taking place in about a week. In the other case the bath was repeated several times, always with good results, both as regards fall of temperature and disappearance of the spasms.—*Lyon Médical.*

Treatment of Burns in Children.—Dr. Wertheimer says that the absorption of some poisonous product would appear to be the most probable cause of death in burns (*British Medical Journal*). This poison has been said to be a ptomaïne not unlike muscarine in action. Ointment-like applications are more efficient than dry ones, although the latter have some advantages, such as not requiring frequent change, etc.; but lymphangitis is more often observed. The object of treatment is to apply some anodyne and antiseptic agent, and to lessen the irritability of the nervous system. Iodoform vaseline is among the best ointments, but the author does not use it in children, owing to the danger of intoxication. Carron oil is a valuable anodyne application, but it is without antiseptic properties, hence the author adds thymol to it (0.05 to 0.10 per cent.). Another combination is an ointment containing bismuth subnitrate and boracic acid, with lanoline and olive oil. The author recommends thymolized carron oil for the first two weeks, and then the above-named ointment, or the latter may be used from the first. Morphine, and sometimes chloral hydrate, may be required internally, but in children under two years they are best avoided. Stimulants are more often needed, even apart from the severe collapse which, in adults, requires prompt treatment.

The Situation of the Respiratory Centre.—The Paris correspondent of the *Lancet* writes that we have hitherto been accustomed to regard the integrity of a tract situated in the medulla oblongata between the vaso-motor centre and the calamus scriptorius, and christened by Flourens *nœud vital*, as indispensable for the continuance of the respiratory function. But Dr. Brown-Séquard has brought to the notice of his colleagues of the Académie des Sciences a series of experiments conducted by MM. Gad and Marinescoy on sixty-five dogs, rabbits, and cats, which lead them to a different conclusion. These physiologists maintain that the destruction of the various centres regarded by Flourens, Gierke, and Mislawsky as centres of respiration, does not involve the permanent arrest of that function, provided certain operative precautions be taken. They further state that there exists in the lower part of the medulla, at some depth from the surface, a mass of cells the destruction of which brings about arrest of respiration, while the stimulation of the same mass determines characteristic changes in the respiratory rhythm. This region, which they are disposed to regard as the true respiratory centre, is not a clearly circumscribed zone, but is composed of a collection of nerve-cells scattered on each side of the roots of the ninth nerve. The centrifugal paths along the cord are direct and occupy the anterior radicular zone.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PULMONARY PHTHISIS IN LATER ADULT LIFE.

THERE is a pretty wide-spread impression, not confined altogether to the laity, that pulmonary consumption is a disease pre-eminently of youth and early adult life, and that it is of exceedingly rare occurrence in later adult life and old age. That this belief is not well founded is shown, however, by statistics, and indeed it would rather seem that the disease occurs much more frequently, in proportion to their number, in the aged than in children. Thus the reports of the Registrar-General of England make the death-rate for phthisis between the ages of fifty-five and sixty-five years greater than between the ages of fifteen and twenty, and between sixty-five and seventy-five twice as great as between ten and fifteen. At the Brompton Hospital for Consumption, out of 800 cases of phthisis in which a post-mortem examination was made, there were 20 cases in people over fifty-five years, and about the same number in children under fifteen; but when it is remembered that there are between three and four times as many children under fifteen years of age as there are of elderly people over fifty-five years, it will be seen that this is, after all, a fairly large proportion of cases of phthisis among the latter.

Dr. Hector W. G Mackenzie, in an article in the *Medical Press and Circular* for October 5, 1892, presents some interesting facts concerning pulmonary phthisis in elderly people, which we may briefly consider here. Of 42 cases in persons from fifty-five to seventy-two years of age, 35 were in men and only 7 in women. In 5 cases the tubercular process was limited to one lung, and in 17 it was much older and more extensive in one lung than the other, so that clinically the disease might have been called unilateral in more than half of the cases. These facts, in regard to age and the limitation of the lesions to one lung, are in accord with the experience of others who have studied consumption in those past middle life.

The author's observations do not, however, bear out the statements made by others, that laryngitis and diarrhœa are infrequent complications of the pulmonary affection. Of 26 cases in which the condition of the larynx was noted, tubercular disease existed in 14, and in 23 out of 29 cases there were intestinal ulcerations. Thus both the larynx and the intestine were involved in an unusually large number of cases. It would, however, be manifestly unsafe to formulate any definite conclusion from the results observed in such a small number of cases.

The symptoms of phthisis in later life are far less pronounced than at an earlier age, and many who are in even an advanced stage of the disease are regarded simply as invalids without any well-defined disease. In some instances the affection simulates in its symptoms disease of the stomach or other abdominal organs. There may be in such cases pain in the abdomen after taking of food, tenderness on pressure, and frequent vomiting, but no complaint of anything pointing to chest troubles. Although the symptoms in such a case would point to abdominal troubles, no growth in that region can be detected on the most careful palpation, whereas examination of the chest will reveal the presence of extensive pulmonary lesions.

Maclachan has pointed out that hæmoptysis is encountered in phthisis of later life chiefly toward the end of the disease, and states that sudden death from this cause not infrequently occurs in elderly people who have never been suspected of being tuberculous. This statement is corroborated by Dr. Mackenzie, who found a history of pulmonary hemorrhage in eleven of the forty-two fatal cases studied by him, and in no less than seven of these it was the cause of death. In two of these there was but one attack of hæmoptysis, in the others there had been several attacks preceding the fatal one.

The duration of the disease in elderly persons is very difficult to determine by reason of the insidious nature of the onset. It is, however, essentially chronic, as is evidenced by the changes found in the lungs post mortem. In one case cited by the author, the patient, a man sixty-four years of age, had complained of slight cough and shortness of breath for six weeks only. He died in about two weeks after coming under observation, and the autopsy revealed the presence of quite old tubercular disease. Owing to the absence in many cases of the characteristic symptoms of pulmonary tuberculosis, the physician would do well always to think of the possibility of phthisis in an elderly patient, when feebleness and loss of strength are very noticeable, especially if in addition a slight cough is present and the person is seen to be falling away in flesh.

THE ST. LOUIS EPIDEMIC.

Two great cities of this country have been suffering from epidemics: Philadelphia from diphtheria, St. Louis from typhoid fever. The development of the epidemic in the latter city has been striking and serious. In October there were about 200 cases, in November over 1,358, increasing from 86 in the first week to 930 in the fourth. On one day 320 new cases were reported. This is something extraordinary in modern times, and unless the progress of the infection soon ceases, St. Louis will outrival Chicago, which had 2,000 fatal, and probably 10,000 non-fatal, cases in 1891. The sanitary authorities of St. Louis trace the trouble to the water-supply of the city. This is taken from the river just below a number of bone-burning and rendering factories.

Sewers which drain a considerable area, in which these factories are situated, discharge their accumulations into the river just above the spot where water for the use of the city is taken. The Chief Sanitary Officer inspected

the source of supply, and the *Republic* refers to his report as follows:

"The Prairie Avenue sewer drains some of the Lowell rendering establishments and empties into the river just above the water-works. 'Within a thousand feet of the present pumping station I found the Prairie Avenue sewer pouring a mass of filth into the river,' says the Sanitary Officer. 'That in itself is enough to contaminate the water. The stench in that vicinity was frightful. In this same district are the Gin Grass Creek and Harlem Creek. The water in both of these is foul, and, of course, emptying into the river so close to the pumping station, has a detrimental and dangerous influence on the city's supply.'"

The citizens of St. Louis have appreciated the danger, and, as we are informed, have been at work extending the mains some distance above the dangerous area. Unfortunately the new aqueduct was not completed in time.

There seems to be no opportunity for severe censure in this case, since the health authorities have been at work for some time in trying to avert the misfortune which has overtaken their city. The epidemic is a forcible lesson in hygiene, though at the same time a tragic and expensive one.

'TWIXT CUP AND LIP.

It is a matter of common notoriety that many a slip can occur between the moment the cup is raised and that when it comes into actual contact with the lips. It is also well known that many a man not only slips and slips again, but may actually fall, because of the too frequent meeting of lip and cup. It has remained, however, for a Brooklyn gentleman by the name of Vanderwerker to point out to the clergy of his city that danger lurks between the lips of their respective flocks and the brim of the sacramental cup. This he has had the courage to do by distributing to all ministers a pamphlet or circular-letter, showing that the prevailing method of passing the cup is uncleanly.

The idea seems to have been entirely new to the preachers, who appear to be unanimous in their condemnation of the author. Medical literature, however, is not lacking in material bearing upon the question, and there seems to be no doubt in the minds of those who have given most thought to the matter, that promiscuous kissing, passing the loving cup at banquets, and the drinking-horn at students' *kneipes*, as well as the prevailing custom regarding the communion cup in the Church, are all open to very serious objection from hygienic stand-points.

Syphilis no less than phthisis may be thus transmitted, and no doubt a host of other diseases, and it must not be thought that church members, who are thoroughly consistent Christians at the same time, are not liable to have contagious syphilitic lesions in the mouth. The syphilis of the family, that acquired in all innocence and possessed in ignorance, is that most likely to be disseminated. Let, then, the Brooklyn reformer take new courage in his crusade against the contagion in the cup, which should indeed be directed against the use, by people in common, of any drinking utensil. Advances in bacteriology make it necessary to reconstruct the time-honored proverb, so that everyone will bear in mind when about to drink from a vessel which has not been properly cleansed 'after having touched the lips of another: "There's many a bug 'twixt the lip and the mug.'

THE SUCCESS OF POST-GRADUATE INSTRUCTION.

The erection of another building for post-graduate instruction, a building more elaborate, costly, and complete than any heretofore attempted, marks a further step in the progress of medical education. It shows that there is a demand for graduate and higher technical medical studies, and that the new system has come to stay. No one who has watched the work of these institutions can fail to see that they do an enormous amount of good. They help to complete the systematic and didactic teaching of under-graduate colleges, they furnish admirably the means for general practitioners to "brush up," and they stimulate them to better and more skilful work. In a measure they are corrective also of some of the evils of excessive specialism. They breed specialists to be sure; but they, still more, give to the general practitioner sufficient technical knowledge to enable him to dispense with specialists in most of the ordinary cases. A physician who goes into a community with some special skill in one or more lines of work soon forces his colleagues to equip themselves also in these lines, and thus he raises the general standard of medical art.

It is but just to remember that the success of post-graduate schools has been attained only by the expenditure of much hard work, which work has not always been sympathetically received. The under-graduate colleges, from not very high motives, have in some cases antagonized the promoters of graduate schools; the opposition, however, has gradually become less, for its uselessness was recognized, and the fact that the two kinds of educational institutions need not and do not conflict has gradually dawned upon the understanding of under-graduate faculties.

Almost Perfect Form.—It is said by those in charge of the silver statue of "Justice," now being made as Montana's mining exhibit at the World's Fair, that Miss Ada Rehan, of this city, was chosen as the model, because out of the sixty-eight measurements which mark the standard of perfect womanhood, in sixty-two she conformed to the requirements, and in none of the other six did she deviate one-quarter of an inch from the standard. It is only doing "justice" by a $\frac{62}{68}$ woman to place her on a $250,000 pedestal.

Claim for Treatment by Prayers.—Dr. F. B. Hyland, of Stoughton, Wis., recently appeared in the Probate Court and presented a claim of $245 against the estate of Phœbe Carter. He said the money was due for one hundred and forty-seven magnetic treatments he gave Mrs. Carter. Cross-examination on the part of the Court developed the fact that Mrs. Carter was in Florida when the alleged treatment had been given, and that the treatment was in the shape of prayers. The Court concluded that Mrs. Carter was not benefited by the treatment, as she was in another climate at the time, and he disallowed the claim. Dr. Hyland took an appeal.

News of the Week.

The Brooklyn Gynecological Society met at their rooms on Friday, December 2d, and elected the following officers for the year 1892–93: *President*, Walter B. Chase, M.D.; *First Vice-President*, George McNaughton, M.D.; *Second Vice-President*, Z. T. Emery, M.D.; *Recording Secretary*, L. Grant Baldwin, M.D.; *Corresponding Secretary*, J. C. MacEvitt, M.D.; *Treasurer*, William Maddren, M.D.; *Pathologist*, J. M. VanCott, Jr., M.D.

The S. D. Gross Professorship of Pathological Anatomy Fund.—The committee appointed by the General Committee to audit the accounts of Dr. Richard J. Dunglison, Treasurer of the S. D. Gross Professorship Fund of the Alumni Association of Jefferson Medical College, respectfully report that after an examination of such accounts, they find that there were sixty contributors to the Fund, the total amount contributed being $3,499.10. In accordance with a resolution of the General Committee, these contributions being insufficient, have all been returned to the donors, and the Treasurer has presented a voucher for each amount thus refunded. A great proportion of the whole amount has been retained undistributed until recently, so that the interest on the amount might so accumulate as to enable the Committee to refund to each subscriber the full amount of his contribution, without any deduction for the expenses of publication of circulars, postage, etc., which were necessarily heavy, from the wide-spread diffusion given the objects of the Fund.

Dr. Henry T. Byford has been elected to the Chair of Gynecology in the College of Physicians and Surgeons, Chicago, to fill the vacancy made by the death of Dr. A. Reeves Jackson.

The Chicago Gynecological Society.—At the annual meeting held October 28, 1892, the following officers were elected: *President*, E. J. Doering, M.D.; *First Vice-President*, Ferdinand Henrotin, M.D.; *Second Vice-President*, Franklin H. Martin, M.D.; *Secretary*, Henry Parker Newman, M.D.; *Treasurer*, A. H. Foster, M.D.; *Editor*, W. S. Christopher, M.D.

Dr. John Ridlon has been appointed Professor of Orthopedic Surgery in the Post-Graduate Medical School of Chicago.

The North Texas Medical Association will meet in Fort Worth, Texas, Tuesday, Wednesday, and Thursday, December 13, 14, and 15, 1892.

A National Bureau of Health.—A bill has been introduced into the House of Representatives by Mr. Payne (Democrat), of Maryland, for the better protection of commerce and the general welfare, and for the establishment of a national quarantine. It is intended to prevent the introduction of contagious or infectious diseases into the United States from foreign countries or from one State into another, and to establish within the Treasury Department the National Bureau of Health. This bureau is to consist of a sanitary council composed of an executive commission and an advisory council. The Executive Commission is to consist of a Commissioner of Quarantine, a Commissioner of Internal Sanitation, and a Commissioner of Vital Statistics, who shall each receive an annual salary of $7,000. There shall be four members of the Advisory Council—the Surgeon-General of the Army, the Surgeon-General of the Navy, the Surgeon-General of the Marine Hospital Service, and an officer of the Department of Justice—who shall receive no additional compensation. The bureau shall meet at the time and place designated by the Secretary of the Treasury. The bureau shall perform all the duties in respect to quarantine which are now imposed on the Treasury Department. It shall obtain information of the sanitary condition of foreign ports from which contagious or infectious diseases may be imported, and also weekly reports of the sanitary condition of ports and places in the United States. It shall make an annual report of its operations to the Secretary of the Treasury. It is made unlawful for any merchant ship from any foreign port to enter any port of the United States except under such rules and regulations as may be made under the provisions of this Act. A violation of these rules shall be punishable by a fine not exceeding $1,000, which shall be a lien on the vessel. All vessels clearing for any port in the United States shall be required to obtain from the consul at the port of departure a bill of health in the form prescribed by the Bureau of Health. This bill of health shall be considered a part of the ship's papers.

The President is authorized to detail officers to carry out the provisions of the bill. The Secretary of the Treasury is authorized to accept, through such steps as may be legally necessary, the possession of all international and interstate quarantine stations and inspection posts. The Sanitary Council shall have authority to forbid entry of vessels from ports known or suspected to be infected with cholera, yellow fever, small-pox, or other declared quarantinable diseases.

American Physicians in Russia.—In his report to the State Department, Consul-General Crawford, of St. Petersburg, calls attention to the fact that a young New York physician, Dr. Blackstein, was chosen by the Russian Government to carry out investigations at Baku, relative to the cause of Asiatic cholera. He also speaks favorably of the introduction of intestinal irrigation by Dr. Lee, of Chicago, into the Obuchol Hospital in St. Petersburg, during the recent outbreak. Dr. Lee read a paper at the last Academy meeting, based on his experience during the late epidemic in St. Petersburg and Hamburg.

Mr. Victor Horsley and Miss Cobbe.—*Apropos* of the anti-vivisection agitation now going on in London, Mr. Horsley has been led, after a study of Miss Cobbe's articles, to write the following: "Further, I have purposely employed this plain language in order to make it clear to the public that Miss Cobbe is unworthy of the customary courtesies of debate. Miss Cobbe has, ever since this agitation began, systematically employed the weapon of deceit, professing, as in the present instance, to quote the whole truth, but in reality suppressing or falsifying the essential particulars. This line of conduct deprives Miss Cobb of all credit, and renders it impossible for me to extend to her the consideration which would otherwise have been due to her sex. I have doc-

umentary (printed) proof that she has chosen, for sixteen years or more, to take an immoral course, namely, accusing medical men of murder, cruelty, falsehood, etc., and, in fact, almost every crime in the calendar, while supporting such charges by frauds of the kind I have now exposed. I cannot, therefore, treat her as I would wish to do; I can in this matter only deal with her quite impersonally, so far as her sex is concerned."

Punch presents this matter as follows:

A Modern Scientific Discussion.

"——Animis Cœlestibus Iræ!"

Miss Fanny (*a gentle and most veracious child*): Yah, you cruel coward! you and your friends skinned a live frog!

Master Victor (*an industrious but very touchy little boy*): You're a liar! The frog was dead, and you know it!

Miss Fanny: Boohoo! Whether it was dead or not, you've got no right to call names; 'cos I'm a girl, and can't punch your head.

Master Victor: It's just because you're a girl that I can't punch yours! You should have thought of that before you called me a coward!

Our happy New York contemporary *Life* is curiously enough on the side of Miss Cobbe. It might learn a lesson in toleration, honesty, and good sense from its London exchange.

The Nebraska Scientific Centre.—A correspondent of the *Omaha Clinic* says: "Many changes have taken place in the faculty, and we enter the session under the most favorable auspices. The New York Medical Record, in commenting upon recent scientific articles contained in *The Clinic*, has failed to appreciate that the Omaha Medical College is the nucleus around which gather such minds, and that it is the faculty of this college that is making Omaha a great scientific centre of medicine. We, as students, cannot fail to see the superiority of this school, which can not only obtain such men, but can use and retain them. Scientific medicine has made rapid advancements in Omaha in the past few years, and the present only indicates the open field which lies before us, and we feel that it is a duty which we owe to our *alma mater* to not only assist in this work, but to push to the front and aid in every way our untiring Faculty."

Obituary.

JAMES R. LEAMING, M.D.,

NEW YORK.

Dr. James Roseburgh Leaming, who died in his seventy third year at his home at 18 West Thirty-eighth Street, December 6th, was among the most eminent specialists of New York City for over a quarter of a century. He had made the study of diseases of the chest a matter for his particular inquiry. He was born in Groveland, Lexington County, on February 25, 1820, and after graduating from the Temple Hill Academy, at Geneseo, he entered the offices of Drs. Edward and Walter Lauderdale, in 1847. After two years of study he came to the medical department of the University of New York, and graduated in 1849. He began the practice of medicine in this city. While he was attending physician at the Northern Dispensary, Dr. George P. Cammann suggested to him that he should devote himself to chest diseases. Even in 1865 he was enjoying considerable celebrity. In 1867 he was made visiting physician at St. Luke's, and when his term expired they created for him an especial office, called special consulting physician, which he held until his death. He was a member of the Medical Society of the County of New York, of the Academy of Medicine, of the Pathological Society, of the Physicians' Mutual Aid Association, and of the New York County Medical Association. He was emeritus professor at the Woman's Medical College and at the Polyclinic, after having been active professor for many years. He read and published a large number of papers, the most valuable of which he collected in his work, "Diseases of the Chest." Dr. Leaming for a good many years had suffered from a complication of lung and heart troubles, and within the last five years these had made him inactive in his profession. Last June he made his last professional call, and since that time he had been steadily failing. He died of phthisis. He had been married three times. His first wife was Jane Helen Cheeseman, of Philadelphia, whom he married in 1853. She died in 1865, leaving him one son, Dr. James Leaming. He married his second wife, Miss Kate L. Strobel, in 1868, and she died in 1888, leaving him a daughter, Mrs. F. W. Meeker, of Grand View on the Hudson. His third wife was Miss Susan Emilia Nelson, daughter of Mr. John G. Nelson. He married her August 14, 1890, and she survives him.

Few physicians of this city have been more warmly esteemed by their professional brethren, and few have had a larger following. Dr. Leaming was a man of strong individuality, and had his own opinions and views, which he inculcated with great earnestness and enthusiasm. In his last sickness he is said to have lamented the fact that he could not auscultate his own chest and satisfy himself of his malady.

JONAS JONES, M.D.,

ROCHESTER, N. Y.

Dr. Jonas Jones, one of the leading physicians of Rochester, died at his home in that city, on Sunday night. He was born in Canada, fifty-five years ago. He graduated from the Bellevue Hospital Medical College in New York, in 1864, and soon afterward was appointed physician in charge of the Rochester City Hospital. He had been Health Officer of Rochester, and was a member of the Board of Park Commissioners when he died. One of his sisters is the wife of James Dundas, a member of the Canadian Parliament.

GEORGE H. BOSLEY, M.D.,

NEW YORK.

Dr. George H. Bosley died suddenly from heart failure on December 3d, at his home in this city, in the fifty first year of his age. He was born in Lakeville, Livingston County, N. Y. He was a graduate of the New York College of Physicians and Surgeons, and served during the civil war as Assistant Surgeon in the army. He organized and took charge of the Relapsing Fever Hospital on Hart's Island, and was connected with the outdoor department of Bellevue Hospital for more than twelve years.

Dr. Bosley was well known in the city as an able and successful physician, and a most estimable man.

Onions are said to act as a preventive of cholera. All that it is necessary to do, according to the advocate of this new and malodorous specific, is to eat onions three times a day or oftener, and to keep the sleeping-room festooned with bunches of the vegetable.

Society Reports.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Fifth Annual Meeting, held in Louisville, Ky., November 15, 16, and 17, 1892.

FIRST DAY, TUESDAY, NOVEMBER 15TH, MORNING SESSION.

THE Association met in the Council Chamber of the City Hall, and was called to order at 9.30 A.M., by the PRESIDENT, DR. J. MCFADDEN GASTON, of Atlanta, Ga.

An Address of Welcome was delivered by DR. L. S. MCMURTRY, of Louisville, Chairman of the Committee of Arrangements, the response to which was made by the President.

Personal Recollections of the Late Dr. Benjamin W. Dudley, of Lexington, Ky., and His Surgical Work.—This was the first paper and was read by DR. BEDFORD BROWN, of Alexandria, Va. The speaker paid an eloquent tribute to Dr. Dudley, and characterized him as the greatest living lithotomist that this country has ever produced, and the most successful in the history of the world. The speaker's close relationship to Dr. Dudley, as private pupil and assistant for two years, enabled him to present a clear and faithful sketch of his character and surgical work.

Experiences in Pelvic Surgery.—This was the title of a paper read by DR. A. V. L. BROKAW, of St. Louis, Mo. Of all the surgical problems difficult to solve, it may be truthfully said that those met with in the pelvis are the most trying. The speaker knew of no surgical work which will compare with the experiences found in the pelvis; a diversity of conditions, complications, and unexpected happenings are ever presenting. In a series of many operations but few will be alike in every particular. As his experience became larger he was free to confess his inability to correctly diagnose the character of abdominal and pelvic troubles. He had diagnosed pus-tubes and found extra-uterine pregnancy, diagnosed extra-uterine pregnancy and found pus; diagnosed ovarian lesions and found the trouble located in the tubes, and *vice versa*. When well-defined pelvic lesions exist, nothing short of radical measures succeed. The one condition above all others where exploratory incision should be adopted, was in cases of suspected extra-uterine pregnancy. It was correct and good surgery to open the abdomen, and not wait for all the classical signs to appear. The symptoms of extra uterine pregnancy were so frequently unreliable and obscure, that he was firmly convinced a radical position should be taken. A case was cited in point.

DR. WILLIAM WARREN POTTER, of Buffalo, desired to endorse that position of the paper pertaining to an early exploratory incision in cases of suspected extra-uterine pregnancy. As regards the use of the sound, he had brought an indictment against it some six or eight years ago, consequently he would not expatiate upon it at this time.

DR. JOSEPH TABER JOHNSON, of Washington, said that as soon as the surgeon diagnosed something in the abdominal cavity that ought not to be there, anatomically or physiologically, and was histologically wrong, it should be removed. An exploratory operation was justifiable in cases of suspected extra-uterine pregnancy, and the surgeon should base his further procedures upon what he finds after making the exploration.

DR. W. E. B. DAVIS, of Birmingham, Ala., thought the pendulum relative to surgical interference had swung a little too far. He believed that a great many of the so-called "tinkerers," who succeeded in relieving their patients, did not accomplish it so much by the local treatment they used, as by having patients under their care, keeping the bowels open, giving constitutional treatment, seeing them regularly, etc. While, by so doing, they might not be cured in all cases, they were greatly benefited. Regarding the diagnosis, surgeons who were opening the abdomen constantly would rarely give a positive diagnosis in the case. Dr. Davis cited the case of a woman who had an acute attack of peritonitis, and the history was the same as from pelvic abscess.

DR. BROKAW, in closing the discussion, said that in every case of suspected extra uterine pregnancy it was good surgery to make an exploratory incision and operate before rupture took place.

Craniotomy upon the Living Fœtus is not Justifiable.—DR CORNELIUS KOLLOCK, of Cheraw, S. C., read a paper with the above title. He said this operation implied the death of the fœtus and a frightful mutilation of its body, often accompanied by serious lacerations of the vagina and adjacent tissues of the mother. Recent advances in obstetrics, gynecology, and abdominal surgery contribute largely to a demonstration of the fact that a timely resort to Cæsarean section in pelvic obstruction is the great factor to success. In Germany, out of 149 cases of contracted pelvis, 109 women and 136 children were saved. If craniotomy had been done in those cases 149 children would have been destroyed, and probably fifty women—perhaps more—making a sacrifice of at least one hundred and ninety-nine lives. In many of these cases exhaustion had supervened and septic influences had already been excited. This, added to a tardy disposition to union by first intention, caused by contusion of the parts involved in the uterine incision, lessened materially the woman's chances for recovery. Zweiffel was successful in 29 cases out of 30; Schauta did Cæsarean section 15 times without a single death. Recently, in 18 operations done in Louisville, 14 were successful. Of 8 in Ohio, 6 were successful. Dr. Price has done Cæsarean section a number of times successfully. Dr. Kollock is firmly convinced that eighty five or ninety per cent. of the cases of obstruction of the pelvis forbidding the delivery of the fœtus in the natural way, might be saved by a timely resort to Cæsarean section.

DR. W. D. HAGGARD, of Nashville, emphasized the position taken by Dr. Kollock. He believes that when the profession fully realizes the immense difference in the number of lives saved by Cæsarean section over craniotomy, there will be no doubt as to its preference to the latter operation.

DR. HUNTER MCGUIRE, of Richmond, favored Cæsarean section. Some time ago he saw the report of a case by Dr. Thomas, of New York, where, in doing Cæsarean section, he proposed to take the uterus out of the cavity, and then open it. He thought this added very much to the danger of the operation, necessitating a larger opening, exposing the cavity of the abdomen a long time to the atmosphere, etc. He does not favor this procedure.

DR. L. S. MCMURTRY, of Louisville, said that a few years ago it would have been impossible for one to have presented the views that Dr. Kollock had, without meeting with violent opposition. Cæsarean section was then regarded as an extremely heroic operation, and until recent years the mortality therefrom was very great; but since it has been carried to the present degree of perfection by Saenger and others, it has strengthened the opinions of abdominal surgeons, who now consider it preferable to craniotomy. Within the last two months symphysiotomy had been brought before the profession and practised, as an alternative in certain cases for Cæsarean section. What the future of the former operation is to be, we were not prepared to say.

DR. ARCH DIXON, of Henderson, Ky., advised Cæsarean section in a case in which he was called in consultation, but the family physician insisted upon him doing craniotomy, which was done, and while every precaution was taken with regard to rendering aseptic the field of operation, the woman developed pelvic peritonitis and died within four days. He believed a Porro operation would have saved the life of the woman, and perhaps that of the child.

A Case of Extensive Hæmatocele Resulting from Tubal Pregnancy Rupturing into the Broad Ligament, was the title of a paper by Dr. W. D. Haggard, of Nashville. Although the fœtus was not found, that it was a case of tubal pregnancy with rupture into the broad ligament, is clearly established by the clinical history and post-mortem appearances, summarized as follows: 1. Patient confessed having had intra-pelvic trouble previously (presumably gonorrhœa), for which she was treated locally. 2. At the time of the accident, caused from jumping from a wagon, her menses were past due. As to how long, her statements were misleading. 3. There was a fitful yet persistent flow from the uterus during her entire illness. 4. Paroxysmal, colicky pains in lower abdominal and pelvic regions of frequent occurrence. 5. Existence of a tumor above the pubes, which she probably mistook for a gravid uterus. 6. Persistent refusal to submit to a digital examination, probably fearing the detection of her pregnant state.

Post-mortem Appearances.—a. Enlarged and softened condition of the uterus, with a patulous os, showing escape of a sero-sanguineal, stringy fluid. *b.* Enlargement of the left tube, with a well-defined cavity from which the fruit sac escaped. *c.* Existence of a deciduous membrane, as revealed by the microscope. *d.* Discoloration of rectum, produced by blood dissection around it, producing constriction and partial death.

Fibroid Tumor of the Uterus—Pregnancy—Rupture about the Fourth Month—Operation.—Specimen, by Dr. S. M. Hogan, of Union Springs, Ala. The woman, colored, was twenty-eight years of age, and from the symptoms and history of the case he was satisfied there was a rupture, and the probabilities were that it was about the fourth month of gestation. He was also of the opinion that the rupture did not immediately destroy the fœtus, that it continued to grow in its abnormal position. The speaker felt sure that if he had operated on the case immediately after rupture, the patient's life would have been saved. In all cases of rupture he would advise Porro's operation to be done immediately; that in all cases where the tumor is large or multiple, intra-mural or subperitoneal, with a sacciform dilatation of the posterior segment of the uterus, and the os above the pubic bone, or inaccessible, the same operation should be done. In all cases where the tumor is in front of the child, or blocking the passage, it should be done, provided the pregnancy has advanced to the full time, or there should be hemorrhage or rupture of the membranes, indicating that an abortion or miscarriage is imminent.

Afternoon Session.

A New Operation for the Radical Cure of Inguinal Hernia, by Dr. George A. Baxter, of Chattanooga, Tenn. Dr. Baxter presented a radically different operation in principle from any yet given. It consists in a prolongation of the incision, after the ordinary management of the sac and after ligation, through the internal ring into a more or less extensive laparotomy, as the exigencies of the case demand; lifting the neck of the sac into the abdominal opening above the ring, and its fixation there by a deep suturing, cutting off the sac close above the peritoneum and its closure by buried suture, and a final closure of the abdominal opening by this and a more superficial set of sutures, which pass across above the closed sac and peritoneum and underneath the deep fasciæ, which are intended to approximate the homologous tissues of the abdominal wall. The ring is closed with crucial sutures dipping over cord and traversing the tissues, and the seminal canal closed with deep suturing alone.

Points of originality claimed: A line of incision suitable for any inguinal hernia, and by the fixation of the sac above the peritoneum a deflection of all abdominal expulsive force from the ring and canal, and the thickened lining of the internal ring, and the method of closure of abdominal incision. Advantages claimed: Quick cure with avoidance of necessity of truss; deflection of expulsive force from internal opening and canal to abdominal parietes. Advantage in being able to approach constriction either from without or within. Avoidance of necessity for traction on sac or contents. Ample room for treatment in diseased conditions of sac or contents, including gut operation, is necessary.

The Cure of Inguinal Hernia in the Male, was the title of a paper by Dr. Henry G. Marcy, of Boston, in which he said, until recently, the cure of inguinal hernia in the male had been considered at the best accidental, and when apparently effected, generally doubtful and the hernia liable to return. The great majority of surgeons looked upon an attempt at cure as ill-advised, and believed operative measures should not be undertaken except in cases of strangulation. Dr. Marcy thought there was abundant reason for such conclusion, when judged from the earlier history of surgical procedures as attempted for cure. The essential surgical considerations for the cure of hernia were as follows: 1. Strict aseptic conditions. These pertain alike to all modern surgical procedures. 2. A free dissection. This is necessary in order to lay bare the internal ring, to permit of the enucleation of the peritoneal sac, and the separation and elevation of the cord out of the wound. The external epigastric artery often courses in the line of the incision. It is not seldom that the size of this vessel is such that the operator fears he has wounded the larger vessel. 3. The disposition of the sac. The separation of the sac to its very base before removal is to be recommended as the rule. There are times, however, when it is not easy to free the peritoneal pouch, owing to adhesions to the surrounding tissues, and in large old irreducible hernia, a more or less intimate fusion of the contents to the inner wall of the sac. It is generally better to open the sac before ligating or sawing through its neck, since by so doing the condition at the internal ring is assured and by such knowledge the operator is often profited, even if the sac is completely empty; not seldom the omentum is adherent at the internal ring, and even a constricted loop of intestine may escape observation when it is attempted to return the sac unopened.

Dr. Marcy closed his paper by saying that between three and four millions of people living in the United States were subject to hernia; and, if the demonstration is complete that the risk of life is less than one per cent. from the operative procedures instituted for cure, and that scarcely more than ten per cent. are subject to relapses, and these almost invariably in a state improved by the operation, the plea is a very strong one, to consider favorably the advisability of operation in a very large majority of all the sufferers from hernia.

The Treatment of Umbilical and Ventral Hernia, was the title of a paper read by Dr. W. H. Wathen, of Louisville. He said the importance of studying carefully the best methods of treating hernia is now especially emphasized, because of the increased frequency of the disease following laparotomy, and especially because the modern methods of surgery make the operation far less dangerous than it formerly was. The operation for radical cure of hernia in the practice of the best surgeons, except in extreme cases, is practically devoid of danger, and the result may be made permanent. Modern antiseptic and aseptic precautions have practically excluded the danger which formerly arose from infective peritonitis. The author said there are many cases of ventral hernia that could have been prevented, had the proper treatment been carried out in the closure of the abdominal wound. In order that there may be no hernia following laparotomy, it is necessary to get perfect union by adhesion of all the layers of tissue forming the abdominal wall— the peritoneum, muscles, the deep and superficial fascia, and the skin; but especially must we get union of the layers of fascia, for unless this be done the other layers will gradually separate, and hernia will follow. This cannot be done unless we succeed in bringing the cut edges of the fascia in even and perfect apposition long enough for strong union to occur.

SECOND DAY, WEDNESDAY, NOVEMBER 16TH, MORNING SESSION.

The Treatment of Ununited Fractures by Resection, was the title of a paper by DR. W. O. ROBERTS, of Louisville. He said the treatment of ununited fractures by resection was more than a hundred years old, White, of Manchester, having done the first operation in 1760. In consequence of the great mortality attending the operation it was abandoned, until revived by Sir Benjamin Brodie. In 1805 Horeau, after having divided the fragments obliquely, fastened them together by tying a metallic wire around them. Rogers, of New York, in 1838, passed the wire through holes drilled in the wall of the fragment, and then twisted it. Since then other surgeons have used sutures of various materials in the same way; some of them leaving the sutures in permanently, while others removed them after union of the fragment had occurred. Some, instead of drilling the bone, passed the sutures simply through the periosteum. Screws, nails, ivory pegs, and clamps have been used for the same purpose. In the long bones, when co-aptation of the fragments can be secured, Dr. Roberts feels satisfied that resection and a fixed dressing will be followed by just as good results as when sutures or other contrivances for fastening the ends of the fragments together are used.

Symptoms of Fracture; Their Importance and Significance.—DR. W. C. DUGAN, of Louisville, read a paper on this subject.

DR. BEDFORD BROWN, of Alexandria, Va., related the case of a boy who sustained a compound comminuted fracture of the skull in 1860, yet he was perfectly conscious and had no symptoms of compression of the brain. The spiculæ of bone were removed, and recovery followed.

DR. J. H. LETCHER, of Henderson, Ky., advised against the too hasty resort to the use of trephine and chisel in injuries of the skull.

DR. C. KOLLOCK, of Cheraw, S. C., had trephined in two cases with successful results.

DR. J. H. MCINTYRE, of St. Louis, reported a case of traumatic insanity in a railroad employee, in which he trephined with success. The fracture was an extensive one and occurred in the upper Rolandic region. He reported several other interesting cases.

DR. WILLIAM WARREN POTTER, of Buffalo, called attention to fracture of the internal table of the skull without fracture of the external; hence the great liability to error in diagnosis.

DR. HOWARD A. KELLY, of Baltimore, related the case of a man who fell and was brought to the Presbyterian Hospital in a comatose state. Careful examination revealed the fact that the man had diabetic cataract with fracture at the base of the skull.

DR. WILLIAM T. BRIGGS, of Nashville, had trephined in fifty cases of epilepsy. Four fifths of the cases operated on were relieved temporarily, but not permanently.

DR. T. A. REAMY, of Cincinnati, mentioned the case of a man who had fallen from the second story of a courthouse, sustaining a fracture of the skull, but had never had epilepsy or any bad symptom following the injury. He thought this case would be some comfort to the country practitioner, who did not enlarge the scalp wound in all cases.

The paper was further discussed by Drs. Vance, Lydston, Nicolson, Greenly, and Dexter, all of them favoring radical measures in the treatment of injuries of the skull.

DR. L. S. MCMURTRY, of Louisville, read a paper entitled "Ovarian Cystoma with Twisted Pedicle and Peritonitis; Ovariotomy in Second Week of Typhoid Fever; Recovery."

Intestinal Anastomosis by a New Device.—A paper was read by DR. H. HORACE GRANT, of Louisville, with the above title. For more than a year the speaker has been endeavoring to perfect some instrument to simplify direct suture, but it has been so difficult to get just what he wanted, that time has not been allowed since the completion of the instrument to test it fully. It is to be used only after resections. The two blades of the clamp are oval scissors one-fourth of an inch in transverse, and two and a half inches in longitudinal diameter. The arms of the clamp are made long enough to allow of introduction full five inches. After the gut is exposed, a strand of iodoform gauze is passed through the mesentery and constricts the intestine fully six inches from each point of intended resection. The mesentery is tied off over the portion to be resected with fine silk, in two-inch loops, cut close and dropped in the usual way. When the resected portion is removed the gut ends may be washed out if desired. While the two ends of the divided intestine are held parallel, one blade is entered in each, allowing at least one and one-half inch of gut beyond the proposed anastomotic opening, to permit of invagination of the ends. The clamp is tightened, and the two surfaces thus firmly held are rapidly stitched together by a continuous overhand Lembert suture of fine silk. Two rows of parallel sutures, as suggested by Abbe, may be used if desired, though it has seemed that one is enough, according to the author's experiments. The work can be done far more rapidly and accurately than without the clamp. When the suturing is finished the clamp is tightened, if need be, and long-bladed dressing-forceps passed in the bowel, and the oval plug removed or pushed in. The scissors action of the blades, together with the ten or fifteen minutes pressure, prevent any hemorrhage. The clamp is now withdrawn and the ends invaginated in the usual way.

DR. A. V. L. BROKAW, of St. Louis, thought the instrument exhibited by Dr. Grant a good one, and said that anything which materially assists the surgeon in making intestinal anastomotic operations rapidly was of great value; that time was a most important element. The use of rings, plates, and mats in the past were bad. He believes that we can suture far more rapidly with Dr. Grant's instrument than with any other device he has thus far seen.

DR. W. E. B. DAVIS, of Birmingham, Ala., believed a large number of operators had abolished mechanical devices in doing intestinal anastomosis. His brother (Dr. John D. S. Davis) had devised a rubber plate and mat, but now prefers not to use the plate. In the case of resection of the bowel, he thought the device of Dr. Grant was an ingenious one, inasmuch as it would facilitate the work of the surgeon and enable him to do an operation very quickly. He had conducted a series of experiments in an effort to do away with mechanical devices, by which surgeons might use the end to end operation by splitting up the bowel. While the operation was successful in some cases, the strain on the circulation was too great, and he now condemns the operation.

DR. G. FRANK LYDSTON, of Chicago, directed attention to Dr. J. B. Murphy's anastomosis button, a recent device, by which he says cholecysto-enterostomies can be done in from eight to twelve minutes. (See page 665.)

AFTERNOON SESSION.

The Association was called to order at 2.30 P.M., with the First Vice-President, DR. C. KOLLOCK, in the Chair.

Annual Address.—The PRESIDENT delivered his Annual Address. He took for his subject "Compatibility of Conservative and Aggressive Surgery." He said the circumspect philosophy of former days taught us, what man has done man may do. But the developments of more recent times say, whatever is practicable may be undertaken, without regard to precedents; conservative and aggressive processes are combined in progressive surgery. Conservatism, in the use of all the appliances of surgery, is not inconsistent with the application of the most energetic means of relief in structural disorders. A misapprehension exists with many of our profession, as to the true sphere of progressive surgery, and it was the

purpose of President Gaston, on this occasion, to make a distinction between rashness in the employment of operative measures, and boldness in the use of surgical means of relief when clearly indicated. Real advances in surgical practice have not been the result of cutting and slashing without due consideration, but have accompanied the painstaking investigation of the conditions requiring the knife, and caution in the performance of operations. As a preliminary to any surgical procedure of a radical nature, correct diagnosis is essential, but to accomplish a proper understanding of a deep-seated disorder it is often requisite to make an exploratory operation of greater or less magnitude. The information based upon such an exploratory measure, serves as a guide to any further surgical procedure. Dr. Gaston said that ignorance and inexperience often lead to sad results in meddlesome surgery, when limbs are sacrificed or organs mutilated to gratify the desire to figure as a bold operator on the part of a would-be surgeon. In such cases no high-toned member of the profession should shield the culprit from the charge of malpractice, or from the assessment of damages by a court of justice.

A Plea for More Rapid Surgical Work.—This paper was read by Dr. Ap Morgan Vance, of Louisville, in which he said a great number of surgeons pay little attention to the time consumed in an operation, or to the nicety of manipulation and dexterous use of instruments that our forefathers prided themselves upon. He had seen on numerous occasions the work of our most distinguished surgeons, and had seen deaths occur from prolonged anæsthesia and too much time consumed in operation, which deaths would not have taken place if much unnecessary time had not been wasted. The habit of starting the anæsthetic before all preparations were completed was very reprehensible.

The paper was discussed by Drs. Arch Dixon, Rufus B. Hall, George A. Baxter, and Edwin Ricketts, all endorsing the position taken by the essayist.

Surgery of the Ureters, with a Report of Cases.—This paper was read by Dr. Charles A. L. Reed, of Cincinnati. He said that surgery of the ureter is one of the developmental subjects of abdominal surgery. These out-of-the-way conduits, exercising functions that are vital in character, were liable to diseased conditions which baffle the resources of the diagnostician and tax the ingenuity of the operator. For purposes of diagnosis, the physical means at our disposal may be briefly summarized as follows: 1. Exploration of the lower end of the ureters by digital examination, (*a*) through the vagina, (*b*) the rectum, and (*c*) the bladder. 2. Exploration of the lower end of the ureters by the sound passed through the urethra and bladder into the ureters. 3. Exploration of the central portion of the ureters by abdominal lumbar palpation—an expedient of practical value only in cases of extreme urethral distention occurring in very thin subjects. 4. Exploration of the upper end of the ureters by exploratory nephrotomy. Each of these several expedients might be amplified, but it would be uncalled for in the presence of such distinguished members. Dr. Reed said that since catheterization of the ureters has been popularized in this country, chiefly through Kelly, and since the technique of the procedure has become understood by those who have studied it, the diagnosis of disease within and surrounding these tubes is vastly more common. The digital exploration through the urethra and bladder is an easy expedient, so far as the surgeon is concerned, and often leads to the elucidation of important pathological facts; but the speaker is forced to believe that it is not without danger to the patient. He has been forced into this belief by one case of incontinence lasting for nearly a year, and by two cases of weakened power of retention, one of which is now of quite two years' standing. Dr. Reed said that abdominal section for diagnosis of urethral conditions, notably in cases of suspected calculus, is entirely justifiable. He then reported a case of peri-urethritis; stricture; kolpo-cysto-urethrotomy, with recovery. The second case was one of cicatricial stricture of an excised ureter; hydronephrosis; nephrectomy, remaining urethral disease.

Specialism in Medicine, Particularly as Related to Surgery and Gynecology, was the title of a paper by Dr. William Warren Potter, of Buffalo. He summarized his argument thus:

1. There is essential need for specialists. Divisions of labor in every field are demanded, and nowhere more than in medicine.

2. Specialists being a necessity, they must equip themselves by years of study, and devote themselves to a still greater number of years of general practice, before they are justified in offering themselves as specialists.

3. They must conduct themselves in such a way as to merit the respect of the general practitioner, and to invite his co operation in their work.

4. The unwritten ethics of specialism demand that there shall be reciprocal relationship maintained, not only among specialists themselves, but also between specialists and general practitioners.

5. The opportunities for perfection in special lines of medical study are so great, and medical literature in both journalistic and text-book form is so rich, that an awful responsibility is entailed.

6. The schools ought to discourage any and all students who give promise of entering upon the practice of a specialty as soon as the college doors are passed, and before the swaddling clothes of the professional tyro are slipped.

The General Practitioner as a Gynecologist.—This paper was read by Dr. R. M. Cunningham, of Birmingham, Ala. He said the general practitioner should not undertake work that can be better and more safely done by the specialist, provided one is obtainable. He should be willing to do and attempt the most radical and dangerous operations when necessary to save life, provided a specialist or one better prepared to do the work cannot be obtained. In cases not necessarily dangerous, or in which life does not become more or less a burden, but in which a cure can be effected only by a radical procedure, but which may be materially benefited or symptomatically relieved by milder methods, he should adopt the latter and not the former. In many cases the field is clearly his own, belongs to him, and he should be prepared and competent to treat them with safety and success.

Specialism in Medicine, was the title of a paper read by Dr. W. F. Westmoreland, of Atlanta. He said there were two kinds of specialists: The one with his preconceived ideas, which become warped, who always suffers from astigmatism, etc., who is a graduate of his kind. The other kind was the man who has worked his way by his generally acknowledged ability in any particular line.

A Preliminary Report on the Morphology of Ovarian and Myomatous Tumors, by Dr. Howard A. Kelly, of Baltimore. The speaker said the form of abdomen characteristic of large ovarian cysts is a globular or ovoid distention of a part or the whole of the abdominal wall, pushing out the infra-umbilical portion much more than the supra-umbilical, at least so long as the tumor occupies the lower half or two-thirds of the abdomen. This enlargement is uniform in parovarian cysts and polycystic tumors exhibiting but few bosses, due to the fact that the latter are composed of one or two large cysts associated with a mass of smaller ones; and the large cyst is best accommodated in the median line in the distended concave anterior abdominal wall, while the smaller ones at the side or back consequently do not show. Prominent exceptions to the general rule just enunciated, that pelvic tumors distend most markedly the inferior abdominal zone, are the notable stretching of the upper abdomen in very fat women with large ovarian tumors, and the like distention in rachitic dwarfs in advanced pregnancy. Nodular myomata, on the other hand, stand out in marked contrast to the smooth outlines of cystic tumors, in giving to the lower abdomen a lumpy, bossed appearance,

thus exhibiting through muscles and skin a softened exaggeration of their irregular outlines. This peculiarity still remains prominent, although softened, after these tumors have undergone fibro cystic degeneration.

Cystic tumors filling the pelvis and part of the abdomen are but rarely found to originate in some upper abdominal tumor. The speaker presented for demonstration a photograph of an enormous kidney, containing over a gallon of pus, extending from the pelvis floor up through the abdomen, and pushing up the left ribs.

THIRD DAY, THURSDAY, NOVEMBER 17TH, MORNING SESSION.

The Present Status of Drainage in Surgery was the title of a paper by DR. A. M. CARTLEDGE, of Louisville. The following summary was presented:

1. The principle of artificial drainage in surgery, while very ancient, was imperfectly understood, and was oftentimes as much a factor for evil as for good.

2. Though our knowledge of the principles which govern a healthy regeneration of wounded structures has greatly advanced, and our progress in wound therapeutics kept pace, we fail to appreciate how artificial drainage can be altogether dispensed with in surgical practice.

3. To lessen the use of artificial drainage it is necessary to thoroughly apply the principles of asepsis and antisepsis, combined with buried sutures, fixation, and alimentary or systemic drainage.

4. Where from any reason the production of a serum cannot be controlled, its removal by drainage is a safer surgical measure than any attempt at sterilization *in situ*.

5. The time required for primary drainage is from twenty-four to sixty hours; to wait longer is to encourage trouble; to remove sooner than twenty-four hours is taking risks not warranted in the premises.

6. Capillary is to be preferred to tubular drainage in wounds other than those of the large cavities. For this purpose absorbable material should be selected, catgut being the best.

7. Where it is desirable to combine hæmostasis and drainage in the same measure, the strips of iodoform gauze, as recommended by Mikulicz, fulfil a most useful purpose.

8. Where natural drainage can be utilized without producing unsightly cicatrices, artificial drainage should be dispensed with; when feasible, combine the two.

9. Wounds involving the brain and cord had best be drained, to avoid mechanical violence to the function of delicate structures by retained serum.

10. Necessity for artificial drainage will most often arise in wounds invading the large cavities; here flexible tubular drains (glass) best meet the requirements, aided or not by materials acting by capillarity.

11. The method of secondary suture after primary wound secretion is over, advised by Kocher, seems to possess no advantage over drains that have to be removed, and certainly is not to be compared in convenience, comfort, etc., to the patient, to absorbable capillary drains.

The Treatment of Tubercular Peritonitis.—This was the title of a paper by DR. WILLIAM H. MYERS, of Fort Wayne, Ind. He said when we have arrived at the conclusion that peritonitis is present, and have discovered the cause, the blow must be struck simultaneously with the onset. No delay can safely be tolerated, the only hope of rescue being the sudden arrest of the disease. By the time that the normal outlines of the abdomen are obscured by tympanitic distention, respiration quickened and shallow, the pulse rapid and wiry, the supreme moment for precise diagnosis is passed. Abdominal section for tubercular peritonitis was the most recent triumph of surgery. Dr. Myers had treated three cases of tubercular peritonitis by abdominal section, washing out the abdominal cavity, and drainage, with complete recovery.

Bacteriological Research in its Relation to the Surgery of the Genito-urinary Organs, was the title of a paper by DR. G. FRANK LYDSTON, of Chicago. The author said that, in his opinion, modern bacteriological and pathological research has nowhere been more productive of scientific and practical progress than in the special field of genito-urinary surgery. He would not attempt to decide the question as to whether, under certain circumstances, the microbial organisms which are constantly to be found in the secretions of the genito-urinary tract, are causal factors in pathogenesis of various forms; or, on the other hand, to decide the precise relation of heterogenetic organisms to the same morbid processes. The relation between what may be termed the normal germ and germs of non-pathogenic properties must certainly be left to the practical microbiologist. We are warranted, however, in drawing certain inferences and making certain practical deductions from what we know of the evolutionary laws of progression, differentiation, and adaptation to environment; many of the diverse forms of disease of microbial origin were doubtless embraced under the omnibus term of urinary infection. The present state of our knowledge does not admit of arbitrary differentiation between them. It is sufficient to say that many forms of organic and functional change affecting the genito-urinary tract are of microbial origin. These processes range in severity from a general infection with effusion and perhaps suppuration in joint cavities, to so simple a local lesion as a chronic prostatic irritation. The author quoted the researches of such modern authors as Reginald Harrison, Halle, Rovsing, Krogius, Bumm, Albarran, and Guyon.

Ovariotomy in Old Women.—This paper was read by DR. JOSEPH TABER JOHNSON, of Washington, D. C., in which he reported three cases, and felt quite sure that prolonged anæsthesia and manipulation within the peritoneal cavity would have proved fatal. The first patient was sixty-seven years of age, and the tumor removed weighed 52 pounds. The second case was one of multilocular ovarian tumor. The patient was sixty-eight years of age, and the tumor weighed 64 pounds. On October 10th of this year, he removed an ovarian tumor weighing 56 pounds from a lady who was sixty-seven years of age, but who looked to be one hundred. Improved methods, quicker operations, antiseptic technique, and provisions against shock, show 33 recent cases, between the ages of sixty-seven and eighty-two, with only two deaths, against 24 cases, done twenty years ago, between the ages of sixty and sixty-seven, with a record of six deaths. These figures demonstrate, in addition to improved technique, the surprising fact that old age is no contra-indication against ovariotomy.

The Simple, Septic, Traumatic, and Specific Forms of Cervicitis and Their Treatment, was the title of a paper by DR. BEDFORD BROWN, of Alexandria, Va. Simple cervicitis arises alone from simple causes. It never originates from infection of any kind. It could exist for an indefinite period without infecting surrounding structures. For many years the author, in the treatment of this affection, has addressed his remedies to the interior of the cervical canal alone, whether he used nitrate of silver, sulphate of copper, carbolic acid, or iodine. Septic cervicitis arises always from septic infection of the pelvic structures connected by lymphatic communication. Contact with the os of portions of putrescent placenta, membranes, coagula, or septic discharges from diseased uteri, were the common causes. Antiseptic measures alone could counteract septic infection and inflammation, whether in the form of septicæmic fever or local inflammatory action. All other agencies were simply palliative or adjuvant in character. Traumatic cervicitis was simply inflammation and congestion of the cervix from wounds inflicted on that body, either during labor, abortion, or from the use of dilating instruments. The author treats this form of cervicitis by means of a solution of nitrate of silver, varying in strength from a scruple to half a drachm, applied in the canal and over the entire cervix. He finds that most of his cases of [illegible]open, and

all cases of concealed, wounds heal by this method. Specific cervicitis may arise either from gonorrhœal or syphilitic infection. In the early stages he resorts to douches containing peroxide of hydrogen in the proportion of one part to three-fourths of boiled water, and also permanganate of potash, one grain to the ounce of water.

Shock.—Dr. James Evans, of Florence, S. C., contributed a paper on "Shock." The speaker said in the severe injuries inflicted on the body by accident, and in the major operations of surgery, not the least element of danger to life is the condition known as shock, which rapidly supervenes. The degree of shock, is not determined solely by the extent and gravity of the physical injury. Certain idiosyncrasies of constitution, the character of the force which inflicted the injury, and the circumstances under which it occurred, are potent factors in its determination. Individuals of a highly wrought and exquisitely nervous organization bear pain with far less fortitude, and are more susceptible to shock than those of dull, obtuse intellects and blunted sensibilities. The author reported a case in point. In laying the foundation of a bridge across the Pee Dee River, in South Carolina, an immense block of granite, weighing over a ton, was being lowered into a pit forty-four feet in depth, at the bottom of which was a man who was to direct when it was in proper position. When this huge block of stone was suspended over the pit the cable holding it began to slip, and the man below was warned to crouch in a corner, as it would inevitably fall. The rock did fall, and the man in the pit miraculously escaped without injury, but he was taken out in a perfectly lifeless condition, and was exceedingly ill for more than a week.

A Manipulative Mistake and its Consequences.—This paper was read by Dr. George Ross, of Richmond, Va. The author related the case of a woman who had suffered from unremitting, agonizing tenesmus, the result of a mass which she carried for seven years in her bladder, and which proved to be on inspection a pledget of absorbent cotton, once saturated with iodine, in shape a truncated cone, and thinly incrusted with phosphate of lime. The patient believed it was introduced by her first physician, who, when attempting to apply any intrauterine dressing, mistook the urethra for the cervical canal.

Harelip Operations.—Dr. William Perrin Nicolson, of Atlanta, Ga., made some remarks on "Harelip Operations," in which he advocated the use of a simple suture instead of a pin, and also recommended paring the edges.

Cholecystotomy, with the Report of a Case, was the title of a paper by Dr. Edwin Ricketts, of Cincinnati, O. He had operated thirteen times for obstruction of the gall-ducts. The patient, a lady, thirty-four years of age, married, consulted him last June. She had never suffered markedly from jaundice, nor from acute attacks of hepatic colic, no marked distention over the region of the gall-bladder; abdominal wall at least three inches in thickness; some general tenderness of the liver elicited by percussion. The patient had the characteristic putty-colored stools, and was losing flesh rapidly. The author advocated allowing a glass drainage-tube to remain in until the common duct was opened, and then, if necessary, to make an anastomosis between the gall-bladder and the duodenum.

Election of Officers.—The following officers were elected: *President*, Dr. Bedford Brown, of Alexandria, Va.; *First Vice-President*, Dr. Joseph Price, of Philadelphia; *Second Vice-President*, Dr. George A. Baxter, of Chattanooga; *Secretary*, Dr. W. E. B. Davis, of Birmingham, Ala.; *Treasurer*, Dr. Hardin P. Cochrane, of Birmingham.

The next place of meeting will be at New Orleans, La., on the second Tuesday in November, 1893. Chairman of Committee of Arrangements, Dr. Albert Miles.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

SPONTANEOUS CURE OF PERITONEAL TUBERCULOSIS—TUBERCULOUS ULCERATION OF PHARYNX TREATED BY LACTIC ACID—"CAISSON" WORK IN BLADDER-SURGERY—THE ADJOURNED DISCUSSION AT THE OBSTETRICAL SOCIETY ON ABDOMINAL SECTION IN PELVIC PERITONITIS—PREVALENCE OF ZYMOTIC DISEASES—REAPPEARANCE OF INFLUENZA.

London, November 19, 1892.

Some interesting facts in regard to peritoneal tuberculosis were brought forward at the last meeting of the Clinical Society. Mr. Lawford Knaggs, of Leeds, related a case in which he had operated for ventral hernia on a young woman on whom laparotomy had been performed, five and a half years previously, for tubercular peritonitis. At the date of the second operation the patient had grown into a healthy and strong young woman; and, on opening the abdomen, no traces of tubercle could be discovered. Mr. Howard Marsh mentioned a case of well-marked abdominal tuberculosis, where laparotomy was performed in consequence of pronounced ascites. Within four or five days the patient began to mend, and she left the hospital well in a couple of months. The behavior of tubercle in the peritoneum was remarkable; there was no doubt that in certain cases the tubercle formation underwent necrosis and disappeared. Mr. Bruce Clark spoke of a case of peritoneal tuberculosis in which he opened the abdomen and irrigated. The patient recovered completely, and no trace of tubercle could be found eighteen months later, when an ovariotomy was performed on the same patient. Dr. Glover narrated the case of a boy, between eight and ten years of age, who was believed to have peritoneal tuberculosis, and in whom hard masses of tubercle were found on rectal examination. The boy, nevertheless, got well without operation. Dr. Goodhart said it was undoubted that tubercular peritonitis might undergo spontaneous cure. He had once made a post-mortem on the body of a lady who had some years previously suffered from a typical attack of tubercular peritonitis; only a few scattered caseous masses were found at the autopsy, but there were numerous adhesions. Mr. Howard Marsh gave a brief account of a case of this kind in which laparotomy was declined, but the patient recovered. Dr. Barlow remarked that the cases which did best were those where a fair amount of fluid was present. These were cases in which there was a deposit of miliary tubercle on the peritoneum, and these were the cases which recovered after, or without, operation. Dr. Hadden said he had made a post-mortem examination in the case of a child whose abdomen had been opened two months before, when the peritoneum was seen to be covered with miliary tubercle. No trace of tubercle was found after death, and the glands were not enlarged or caseous. The President (Sir Dyce Duckworth) said that in no part of the body did tuberculous lesions fare better than in the abdomen. He agreed that the most favorable cases were those in which there was some ascites.

An encouraging example of successful treatment in tuberculosis was brought before the Medical Society of London, at its last meeting. Dr. Percy Kidd showed a woman who presented simply a large cicatrix of the pharynx, with some small nodules over the base of the tongue. Last Christmas she was suffering from tuberculous ulceration of the pharynx, associated with a good deal of pain—especially on swallowing. He applied cocaine, and then brushed the pharynx over with a fifty per cent. solution of lactic acid. Later on the pure acid was applied, and thorough cicatrization ensued.

At the same meeting of the Society, Mr. Hurry Fenwick made a communication on what—borrowing an engineering term—he termed "caisson working" in blad-

der-surgery. The method he employed was as follows: The patient was nearly always placed in the Trendelenburg position. Rectal bags were not used. The bladder was then opened above the pubes—the opening being made just large enough to admit a thin white porcelain cylinder, which was sunk, without allowing any of the water in the bladder to escape, onto the spot where he had previously ascertained, by the use of the electric cystoscope, that the tumor was placed. The cylinders were of various lengths and sizes, according to the thickness of the parietes, the depth of the bladder, and the size of the area to be operated on (in his first case he had used a Ferguson's speculum). A Jacques catheter was placed in the cylinder when it rested on the bladder and siphon action established by suction from a syringe; the water was thus run out of the caisson and the tumor seen, dry and bloodless, at the bottom. By throwing in a beam of electric light, by means of Dr. Washington Isaac's incandescent "search-lamp," it became possible to remove the growth by forceps, with extreme accuracy and thoroughness. The method had proved of special value in the early stages of benign tumors, where the growth was often very small—also in removing small, sessile, secondary splashes of villous growth, which were often left behind untouched or unrecognized by the finger, after the main piece of the tumor had been wrenched or scraped off. If vesical growths were operated on earlier, the mortality of the actual operation would diminish, and even in epitheliomatous degeneration of the mucous membrane a cure might in some instances ensue. Mr. Fenwick said he based this belief upon an experience of over 100 cases of tumor of the bladder. The method could be used in bladder growth for curetting or cauterizing definite catarrhal or tuberculous ulcerations, for incising the mouths of sacs of encysted stones, and for marking out the lines of enucleation of the intravesical growth of the senile enlarged prostate. It was unfit for contracted bladders. He recommended the procedure on the grounds that only a small incision was necessary; that it avoided bruising and tearing of the bladder by the continual passage of fingers, etc., through the wound and bladder incision; that not only the main growth but the smallest patches of primary or secondary growth could be seen and accurately treated by shifting the caisson from place to place; that the base of the growth could be cauterized by means of a galvano-cautery point with safety and certainty, and because bleeding could be easily arrested before the patient left the table.

The adjourned discussion on Dr. Cullingworth's paper on "Abdominal Section in Certain Cases of Pelvic Peritonitis" was brought to a close at the last ordinary monthly meeting of the Obstetrical Society. A great want of unanimity among the speakers was evinced, so the debate cannot be said to have led to any definite conclusion. Dr. Gervis resumed the discussion, and remarked that if the title of the paper were carefully considered some of the objections taken to it would be lessened. Dr. Cullingworth had only proposed operative procedures in certain cases of pelvic peritonitis, and these would appear to be cases of recurrent peritonitis associated with "distinct swellings in the posterior quarter of the pelvis;" he would not hesitate to agree with this proposition of Dr. Cullingworth's. Mr. Mayo Robson said he preferred to discuss the subject on general principles. We did not hesitate to open and drain an abscess in the neighborhood of the cæcum, so as to obviate its bursting into the peritoneal cavity; why should there be any argument as to the propriety of dealing with a pelvic abscess on similar principles? Mr. Knowsley Thornton said the result of a careful study of Dr. Cullingworth's paper was to deter him from performing these operations. The mortality of eighteen per cent. could not in any way be justified by the mortality of the diseases themselves when let alone. Mr. John W. Taylor said he heartily agreed with the general tenor of every one of Dr. Cullingworth's propositions. Dr. Heywood Smith said ventral hernia had been mentioned as of frequent occurrence after abdominal section, but such an accident did not often happen, and was not to be weighed against the chronic invalidism and pain that the operation was intended to obviate. He entirely agreed with Dr. Cullingworth's proposition that it was safer to attack cases of pelvic suppuration from above than from below. Dr. Griffith said gonorrhœal salpingitis had been spoken of as frequent, but his experience was that it was neither easy nor common to obtain satisfactory evidence of the gonorrhœal origin of pelvic inflammations. Mr. Skene Keith drew attention to the length of time which often elapsed before recovery was complete in these cases. Dr. Cullingworth replied at some length in defence of his propositions.

Zymotic diseases are very prevalent. The metropolitan epidemic of scarlet fever shows some signs of abating, but the disease is spreading in the provinces. Both measles, small-pox, and diphtheria are also very active. Influenza has reappeared, and one death is reported at Greenwich.

New Instruments.

A COMMON-SENSE BED-PAN.

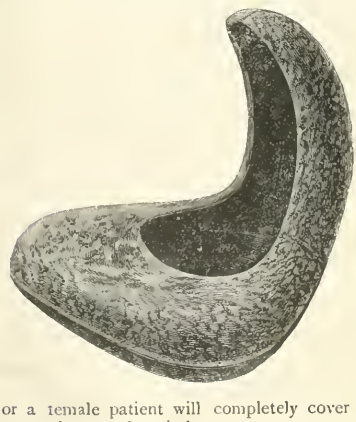
By LEONARD W. BACON, JR., M.D.,

NEW HAVEN, CONN.

I WOULD like to call attention to a new bed-pan, designed in the hope of providing, for patients unable to leave their bed, a more convenient and comfortable utensil than has hitherto been procurable in the market, and, at the same time, of furnishing their attendants with an instrument which can be kept easily and readily in that cleanly and aseptic condition so absolutely necessary in an instrument of the kind, yet so difficult to attain with the ordinary form of bed-pan.

This new instrument is a radical modification of a bed-pan designed by Hermann Haertel, of Breslau, and made and used in Germany.

From this German instrument was derived the "horn," seen in the cut of the bed-pan below, which is intended to come up between the patient's thighs, and in either a



male or a female patient will completely cover in the perineum and external genitals.

By this device the urine and fæces, no matter with how great force they may be expelled, are conducted into the body of the pan beneath, without possibility of failure, and without the necessity of special adjustment or manipulation on the part of either nurse or patient. The inconvenience of having to use a "duck," or urine bottle, at the same time with the bed-pan, is thus done away with.

In cases of perineal section, or other conditions involving incontinence of urine or of fæces, the bed-pan which I have designed can, because of its careful adaptation to the anatomy of the parts, be left for some hours under the patient without discomfort or danger of bedsores. The "diaper," commonly in use in such cases, is at best an uncomfortable, inconvenient, and even a dangerous thing on account of the maceration of the skin and the chances of infection. As compared with the "diaper," a comfortable bed-pan is certainly a distinct improvement.

The cover of the pan proper, upon which the patient's sacrum and buttocks rest, is carefully moulded to fit the parts. On either side there is a boss in the cover, coming just external to the posterior spinous processes of the ilia. These bosses form between them a shallow trough which receives the sacrum comfortably, while a due proportion of the weight of the body is supported upon the fleshy part of the buttocks, instead of resting entirely upon the bony structures of the sacral region.

The instrument in question does not form a wedge behind as most bed-pans do, but is thickest at the posterior edge of the pan. A little thought will show that this conforms to the anterior convexity of the lumbar spine. In fact, when a patient is placed in position with his buttocks elevated upon one of the old "shovel" bed-pans, the weight of the patient's trunk rests entirely upon the buttocks and the shoulders, so that there is room at the end of the bed-pan to place the open hand, edgewise, between the bed and the small of the back. The only exception to this would be in the case of a patient in the most extreme degree of relaxation and debility, and even then only with the thighs flexed on the abdomen. In these cases, when the body is doubled together in such a bent and unnatural position, the acts of urination and defecation are performed at great disadvantage and often with much difficulty, as the abdominal muscles have not the opportunity to exert their pressure and the expellent forces have to work literally "up hill."

The form which I have given to the posterior end of my bed-pan, while it does not necessitate raising the patient's buttocks any higher than do other bed pans, at once takes advantage of this waste space to increase the capacity and facilitate the cleansing of the instrument, and, for the feeble, provides a comfortable support to the back as high as the third lumbar vertebra.

The number of patients acutely ill, who, in spite of their best efforts to use a bed-pan in the recumbent posture, find it extremely difficult or impossible to do so, is by no means small. The physician, when he calls, not infrequently learns to his chagrin that his typhoid or puerperal patient, upon whom he has most strictly enjoined the recumbent posture, has been out of bed to attend to the wants of nature, despite his injunctions as physician and the best efforts of patient and attendants, to obviate the awkward difficulty. In such cases the new bed-pan is especially serviceable.

If the instrument is adjusted under the patient while lying down, and is placed, as it is intended to be placed in all cases, with the horn close up to the perineum, the patient, if feeble, may then have his shoulders propped up as high as may be necessary with pillows, or, if stronger, may raise himself into the completely sitting posture if he desire; the bed pan meantime will follow the movement of the pelvis, and will tilt forward like a rocking horse, being still entirely comfortable under the patient, who is in no danger of slipping off, or of soiling himself, or the bed, or of over-filling the pan, as provision has been made in the design to have the capacity of what would then be the lowest part of the instrument ample to receive any dejection.

The convenience of the nurse or attendant has been as carefully studied as that of the patient. The smooth, hard finish of the well-known agate-ware offers a surface as readily cleaned as china, while its lightness, as compared with crockery, reduces the weight of the instrument very materially. This bed-pan has no corners and every point in it is readily accessible to the hand.

The contents of the pan, whether solid or liquid, can be poured out through the horn of the bed-pan as through the nose of a pitcher. This bed-pan has a much greater capacity than the old "shovel" pan; it may also be held in almost any position without overflowing. A specially advantageous feature lies in the fact that this bed-pan can be easily carried with one hand, even when full, without danger of dropping the pan or spilling its contents.

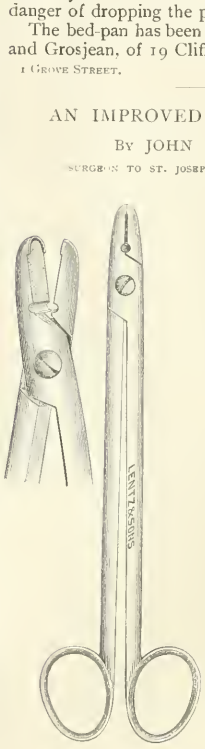
The bed-pan has been made for me by Messrs. Lalance and Grosjean, of 19 Cliff Street, New York City.

1 Grove Street.

AN IMPROVED SHOT COMPRESSOR.

By JOHN S. MILLER, M.D.,

Surgeon to St. Joseph's Hospital, Philadelphia, Pa.



Complicated surgical instruments, even if efficient, are not generally welcome to the surgeon. Simplifications of all details in rendering them aseptic, is most desirable. If an instrument can be made to do the work of two, and its mechanism is not complicated thereby, we would believe this to be an effort in the right direction. In gynecological operations where silkworm gut—or any other form of suture—is used with shot, a shot compressor is required, and also a pair of scissors to cut off the ends of the sutures. The instrument depicted in the woodcut is simply an ordinary shot compressor with simi-circular cutting edges at the points of both jaws. After the shot is compressed the instrument is slightly withdrawn and the suture is cut off, thereby saving time and lessening the number of instruments.

PRACTICAL EXPERIMENTS IN THE TREATMENT OF CHOLERA IN ST. PETERSBURG, RUSSIA, AND HAMBURG, GERMANY, IN THE EPIDEMIC OF 1892.

BY ELMER LEE, A.M., M.D., PH.B.,

CHICAGO, ILL.,

MEMBER OF THE AMERICAN MEDICAL ASSOCIATION; FELLOW OF THE AMERICAN ACADEMY OF MEDICINE; MEMBER OF THE CHICAGO MEDICAL SOCIETY, ETC.

THE result of the investigations made by men of many countries during the epidemic of cholera of 1892 which visited Europe and Western Asia is not yet fully reported. The intervals of epidemics of cholera are so wide apart that a continuous study of the practical side of prevention and cure is interrupted. By comparison the epidemic of 1892 in Europe has been more destructive than any epidemic during the present century. The whole number of deaths in Russia will amount to 200,000 souls. The rate of mortality has been on the average nearly fifty per cent. of all cases sick with the disease. This rate of mortality is almost the same as the rate which has existed in every epidemic of the century.

The promises that have encouraged Europe to believe that the time was near when epidemic diseases could be controlled by the knowledge gained through bacteriology have not been realized. The interesting work of the scientific laboratory has raised universal hope in every land; the expectation of relief from this storehouse of scientific wisdom concerning the nature of the real or supposed causes of cholera has not been able, during the epidemic of 1892, to lessen the mortality from cholera. Before the knowledge of the relation of bacilli to enteric diseases the death-rate was no greater than during the summer of 1892. The laboratory researches filled us with expectations of relief which were seldom capable of practical demonstration, and particularly is this true of cholera. While the scientific discoveries have been centred in Europe it has unfortunately been found that Europe is no better prepared to resist the spread of the epidemic diseases than are those countries in which there has been no laboratory science whatsoever.

The interesting and the practical side of an epidemic is to save the people from disease and from death. Whatever may be said by me is the result of experiences and observations in the cholera regions of Russia, Germany, and France during the summer of 1892. The views which will be expressed are the result of individual observation, and it is not my intention to present either statistics which have been presented before, or to at any length present opinions that may be either agreeable or contrary to the views taken by myself. The paper will be concerned with the experiences and the impressions that have been made upon me personally by actual contact with the practical side of the treatment of the disease of cholera.

A visit to Europe was undertaken for recreation and pleasure early in last May. When in Paris, during the month of July and the early part of August, information was received that cholera was epidemic in Southeastern Russia as well as in Western Asia. Further information from time to time showed that the epidemic was spreading to regions more or less remote, both north and west. There were at the same time reports of cases resembling cholera in various parts of France and in Paris.

When the cholera had reached as far north as Nijn Novgorod, and a short time later to St. Petersburg, the thought came to me that it was a duty that I owed to science and to humanity to go to these places and there determine the value of the views entertained by me concerning the practical management of an epidemic of cholera. These views were indicated to colleagues in Paris, information was sought in many directions in order to ascertain if the method which was to be proposed by me had been anticipated. During this investigation some slender reports came of a few cases of cholera in Havre and in Hamburg, but having determined to go to the centre of the cholera region, it was decided by me to carry out the plan of visiting Russia. So far as my investigations went among colleagues in Paris and also in Berlin, it was not learned that my system of cholera treatment had been anticipated.

The knowledge of the pathology of cholera was not clearly defined in my mind, but that it more nearly resembled a general entero-colitis than anything else was the first basis upon which my reasoning was founded. The information which had been derived from a study of the text-books concerning this disease had not been entirely satisfactory and conclusive. One view which seemed to be almost universal was that cholera is a disease resulting from the introduction of filth into the stomach and intestinal canal. This no one had ever disputed, and upon this basis, as a foundation for further thought, I built my plan of dealing with the disease. I said to myself that if cholera is the result of a filth taken into the stomach and intestinal canal, it is desirable, then, to do two things: one is to prevent the introduction of the filth into the body through the mouth, and the other is, the filth having been taken into the body through the mouth, the rational manner of treating the disease would then be to remove that filth in the most prompt manner.

The prevention of disease was the especial concern of the general and local boards of health and sanitary committees, and the responsibility of governments and communities. My direct connection with the necessities of the epidemic consisted in the practical means that would save the sick from suffering and from death. Finding that it was agreed by all medical men that cholera is dependent on filth which has been introduced into the stomach and intestines, it seemed to me that but one road was open to save the lives of cholera patients. If the disease depended upon an accumulation of products, of whatsoever nature and by whatever name they might be called, and these products could be removed from the intestinal canal, it seemed to me to offer a promise of cure to the cholera patient.

It had been determined by me, by a large and varied experience in America, before visiting Europe, that it was not only possible but practicable to empty the small intestines of their contents by a surgical procedure consisting of the introduction of an irrigating solution into the colon. Could this truth be demonstrated and proved upon actual patients in the cholera regions of Russia it would not only be creditable to the profession in America but it would alleviate very much suffering and go far to reassure the people that it was possible to treat cholera with better success than it had been treated up to that time.

I believed in the proposition so earnestly that I was willing not only to give my time and my services to the

Russian Government, but also to bear the necessary expense, in order to gain for myself the experience, which, if satisfactory, would be of use in the event of epidemics of cholera in my own country.

The proposition was made to the medical staff of the Oboukoof Hospital in St. Petersburg. The chief physician and his assistants said they could see no objection, and that it was their wish to afford an opportunity for a practical demonstration in cholera cases upon the plan presented by the American physician. At that time the cholera was at its height throughout all Russia, and there were reported in St. Petersburg, as many as six hundred cases of cholera in a day; in the hospital to which I was admitted there were one hundred cases. Not all the cases of cholera in St. Petersburg were treated in the hospitals, it was not obligatory upon the sick to go to a hospital, but, if upon investigation by the physician of the department of the city in which the case was reported, it was thought to be desirable for the best interests of the neighborhood as well as the individual, the patient would be removed to the hospital. The unfortunate prejudice which prevails in Russia among the poorer people against hospitals and physicians made it always a difficult matter to secure the co-operation of the friends of the sick and an early report of their sickness. Many cases would be kept from the knowledge of the authorities by the family of the sick, in order to avoid either the physician or the hospital. This prejudice is found everywhere in Russia, and is the inheritance of the people from their Asiatic origin.

The treatment of the sick brought to the hospitals is notably humane and kind, no country can be said to treat its sick with more consideration and skill than does Russia. The hospitals are marvellously well arranged and remarkably clean, and the system of protecting the sick from unsanitary and unwholesome influences would challenge the respect of the whole world. The physicians are men with large hearts and great ability, and in no country that has been visited by me have the physicians so reminded me of the profession at home as do the medical men of Russia. The appliances, and the general application of modern and approved ideas of the management and treatment of patients was to be found in a high state of perfection in the hospitals of St Petersburg. An American physician could not help but be deeply impressed with and mindful of the excellence and the scholarly attainments of the Russian physicians whom he would meet at these hospitals.

As soon as the formalities incident to the arrival of a foreign physician in a Russian hospital could be dispensed with, a practical opportunity for the treatment of cholera was afforded me. The proposition, which was made to the Russian physicians through a medical interpreter, consisted of the following plan of treatment:

I said to them that it was my belief that if the contents of the intestinal canal were removed at a time before the blood was overwhelmed with the absorption of the poisons from the intestinal canal, it was reasonable to expect satisfactory results; that this plan contemplated the practical application by myself of the proposition. The manner in which I proposed to experiment was stated to them and it received their approval.

The plan consists of the introduction of a soft rubber tube one metre in length, and of suitable size to be introduced into the rectum, in front of the promontory of the sacrum, into and up through the sigmoid flexure and into the descending colon. The tube, as has been found by experiments, should not be too small nor yet too large, in order to facilitate its introduction through the obstructing folds of the sigmoid portion of the lower bowel; the greatest difficulty which would be encountered would be to successfully pass the tube in front of the promontory and enter it into the sigmoid flexure. The size that has been found to pass the most easily is a tube that would correspond to a No. 48 in diameter, according to the French measurement. Smaller tubes may be introduced, but the interference by the pockets of the twisted sigmoid offer more resistance to the introduction of the smaller tube than it does to the larger one. It is also of the greatest importance that the tube should be of proper firmness to prevent it from bending or buckling upon itself when the end, which in all cases should be rounded, comes in contact with the obstructing fold of intestine. The tubes which were used by me in St. Petersburg were not of the kind that would most readily meet with the requirements, but, with a single exception, I believe the sigmoid and the descending colon was reached by the tube in every case treated by me personally. That there is difficulty in passing the promontory I am anxious and ready to admit, but that the difficulty is not necessarily so great as to prevent the introduction of a suitable tube I also maintain. The introduction of the tube is favored by the flow of the irrigating solution from its open end, in that the force of the flowing stream helps to lead the way in the twisting bowel into which the tube, when gently rotated and urged forward, may be made to pass. By this system of inducing a running stream of water, suitably medicated, into the colon, it is reasonable to expect to introduce the water as far as the ileo-cæcal valve, and I am satisfied that in suitable cases, when the pressure against the cæcum is sufficiently prolonged, the valve opens and admits into the small intestine some part of the water from the colon. This proposition is not necessarily new to my colleagues, but it is not entertained by all with whom I have conversed. But there is a principle which is, I think, sufficiently important and new, so far as its recognition is concerned, to justify a strong hope of splendid results in the future by the use of irrigation of the colon. The effect of a flowing solution of water through the colon, from the end of the conducting tube and back through the colon, through the sigmoid flexure, and into and out of the rectum through the opening which is made by the relaxation of the sphincter ani muscle, is to successfully and actually clean and purify the large bowel and all that is below it. Secondarily, the effect of the running stream upon the living tissue carries a sympathetic impulse to the muscular mechanism of the small intestine, which is equivalent to an increased peristaltic action of this part of the canal. By actual experience it has been demonstrated, to my own satisfaction and to the satisfaction of my Russian colleagues, that the secondary effect of irrigation of the colon is to cleanse and relieve the small intestine of its contents. The recognition of this splendid secondary effect gives the irrigation system, in the treatment of cholera, a usefulness which promises to revolutionize the treatment of cholera in the Russian Empire. The effect of passing into, through, and out of the large bowel a quantity consisting of two or three gallons of warm water, preferably medicated with soap, is not only to directly remove the accumulated contents of the large bowel, but secondarily, through the sympathetic nervous action of the muscular organism of the small intestine, to almost completely carry off its liquid contents, including every form of bacterial life. The value of this lesson had been learned by me in the treatment of various forms of entero-colitis, and to learn the value of the lesson in the treatment of that form of entero-colitis called Asiatic cholera induced me to set aside plans for recreation and pleasure and to go and prove for myself, and afterward for my assistants, what value the complete, thorough, and systematic irrigation of the larger bowel would have upon the different stages of cholera. When the intestinal canal is cleared of the hurtful and filthy mass which it contains, it gives great relief to the cholera patient.

I began my experiments at the Russian hospital under considerable difficulty, owing to the fact that I was unable to speak the Russian language, and there was, therefore, a lack of complete understanding of each other, but as soon as the first experiment had been completed the Russian chief physician expressed his satisfaction at the good results which were secured and ordered that further

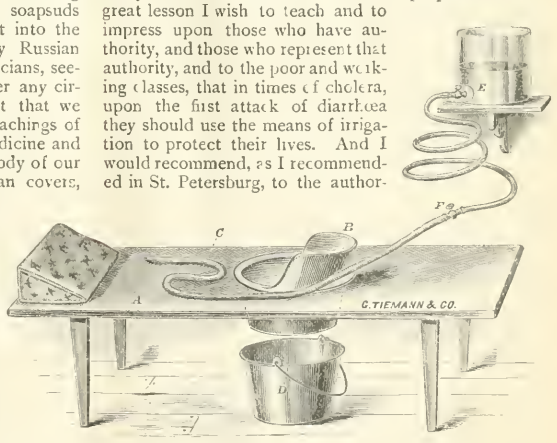
cases be provided for me. The second case treated by me resulted satisfactorily, but the treatments were made under unsatisfactory conditions, because the conveniences that were required had not yet been provided; still, the effects were so good that the co-operation of the physicians was soon secured. I strongly insisted from the first that to expect the full benefit from the irrigation the cases should be treated from the earliest moment of their arrival in the hospital, and finally the privilege of treating patients upon their arrival was accorded me.

The plan, as finally adopted, was to take the patient directly from the ambulance to the bath room, without delay, and when the clothes were removed the patient was laid on his back on the irrigating table with the knees drawn up and the muscles of the abdomen relaxed; then, without any waste of minutes, the long tube, after being lubricated with soap, was gently pushed into the rectum and urged by twisting and gentle pressure into the lower bowel as high as the tube could be made to go, and the stream of the previously prepared solution of warm water and soap, making a soapsuds, was allowed to run as freely as the tube would permit, into the colon, and when the colon became filled the pressure exerted would force the water to seek an outlet back through the bowel into the rectum and out of the opening around the outer surface of the tube into a properly constructed receiving vessel. I remember on one occasion calling the attention of the chief physician to the great and stinking mass of putrid matter which the stream of soapsuds had washed out of the intestine of a peasant into the receiving vessel, I made the remark to my Russian friend, how it was possible we modern physicians, seeing the nastiness before our eyes, could, under any circumstances, indulge ourselves in the thought that we were treating our patients according to the teachings of our enlightened civilization and antiseptic medicine and surgery; when we washed the surface of the body of our patients and laid them in beds, between clean covers, with such a quantity of putrefying, decomposing filth left in the intestines of these outwardly clean patients, every minute they laid in their supposed security their blood was feeding upon the foul poison that filled the intestinal canal. One of the strong practical medical lessons of my life is brought to me when I see the filthy contents of the bowels after their removal from the patient.

In my treatment, after the bowels of the patient have been cleansed he is then placed in a bath of warm water and afterward conducted to his bed, not only clean outside but, if not wholly purified as to the intestines, at least enough cleaner to promise freedom from further infection.

I have found that soap consisting of oil, potash, and glycerine, when added to warm water, is a disinfectant of the highest importance, and it is my conviction that the addition of drugs and chemicals of any nature only serve to complicate and confuse without improving the soapsuds solution in its value as a treatment of cholera bowels. I have experimented with many of the old and many of the new antiseptics and disinfectants added to the warm water irrigations, and am of the opinion that soap-and-water meets the requirements perfectly. Whenever it is thought necessary in the treatment of cholera the irrigation is repeated one or more times. The average number of times that irrigations were given in the treatment of cholera in St. Petersburg was twice, occasionally a third irrigation would be given, but frequently one irrigation was found sufficient. Within one or two hours after the soap-and-water flushing of the lower bowel the patient would have from one to three or four evacuations, which would be followed by an interval of rest and cessation of from twelve to twenty four or thirty-six hours. The relief of the spasm of the intestinal muscles, which produces the intense suffering, followed promptly upon the removal of the irritating contents, and the administration of morphine would not be required. In addition, whenever it was thought desirable—and it was thought desirable in nearly every case—the stomach was cleansed by irrigating it with a solution of salt and water. After this combined treatment, as soon as the patient was quiet, vomiting and purging, in most cases, would subside. As an internal treatment I recommended and used hydrogen dioxide diluted with distilled water, given in cupful doses at intervals of three hours. The object of the administration of the hydrogen dioxide was to further cleanse and disinfect the intestinal canal, and the distilled water was added to increase the bulk and remove the raw and objectionable taste of the hydrogen.

A plea was made by me to establish this system of treating cholera at the time of the first symptoms of the disease. The first symptom of cholera is a preliminary looseness of the bowels or a diarrhœa. The diarrhœa is the signal of warning which may be recognized by the most ignorant and careless peasant, as well as by those who are higher in the social scale. I believe that if all cases without waiting for a confirmatory diagnosis to be made by the bacteriological examination of the discharges, were brought under the influence of this treatment as a system of management, it would be reasonable to expect recovery in times of cholera, if not an entire escape from the disease. This last proposition is the great lesson I wish to teach and to impress upon those who have authority, and those who represent that authority, and to the poor and working classes, that in times of cholera, upon the first attack of diarrhœa they should use the means of irrigation to protect their lives. And I would recommend, as I recommended in St. Petersburg, to the authorities, the establishment in the districts of towns and cities of a simple but effective apparatus, to effectually cleanse the bowels by a process of irrigation with soap and water.



The irrigating apparatus is simple and would consist of a low table suitably made, which is represented in the accompanying illustration. The necessary apparatus required for irrigation has been provided, according to my drawings and directions, by the progressive house of Messrs. Tiemann & Co., of New York. I would have such an apparatus provided near the home of the poorer classes, as well as in every part of the city, and a physician detailed to receive and treat every man, woman, and child who should come with any symptom of looseness of the bowels or abdominal colic. Then, if thought desirable, the patient should be transferred to a hospital, or permitted to return home.

The loss of time between the first symptoms of cholera and the time of treatment is fatal, and this simple lesson should be taught, by the use of clean, wholesome English, to all the poor and the working classes, and they be made to realize the reasonableness of this plan of action, which would go far toward relieving the anxiety and terror that is present in cholera times. The public mind is overwhelmed with the feeling that cholera is a mortal disease,

and this feeling is increased by the unfortunate necessity that physicians are from time to time obliged to state that no treatment has been found satisfactory.

It will be interesting to recite my experience in the treatment of a Russian peasant boy, sixteen years old, who entered the Oboukoof Hospital in the morning with the typical symptoms of cholera, consisting, as it did in his case, of profuse vomiting and purging, with a cyanotic skin and cramps in the knees and other joints, as well as a colic from which the poor boy was bitterly crying between the intervals when he would vomit. When my Russian colleague and myself visited this boy upon his arrival, I was asked if I would treat this case, being a very severe one, to which I gladly responded, yes. He was removed to the wash-room and placed on his back on the low irrigating table, with his hips fitting into the basin, and the bowels were washed with the warm soap-and-water, the tube being introduced by myself. The effect was most gratifying. The bowels were relieved of a large quantity of nastiness, which made the patient slightly more comfortable at that time. He was next lifted into the bath of warm water and afterward conducted to his bed. He received during that day small cupfuls of diluted hydrogen dioxide as his only medicine. When I returned next morning to the barracks the Russian physician asked me if I had seen our patient, and I said no, fearing that possibly some misfortune had occurred. Whereupon, seeing my anxiety, he relieved me by saying, "Our patient is quite well." We went into the ward to look for the patient, but he was not there. We looked in other wards but could not find him, and did not find him in the barracks anywhere. The day was warm and bright and the boy was feeling so good that he had eluded his nurse and slipped out into the open air, where we found him seated on a bench with the convalescents, in a happy state of mind. This patient, it is hardly necessary to remark, was a great pride to me, and I may state that he received no further treatment in the hospital but was detained for a period of one week as a measure of prudence, which is the rule in the case of all convalescents.

The number of cases treated by me personally according to this system of management was 27; the total number of deaths were 3 and the recoveries 23, with one whose recovery was not complete at the time of my departure.

The number of cases treated by my system in the hands of the physicians of the hospital amounted to nearly one hundred at the time of my departure, but the final records of these cases are yet to be published.

The number of cases treated are not sufficient to entitle the system to more than a statement of the facts and a plea for further experience at the hands of other clinical physicians. The hospital staff in St. Petersburg accepted the lesson taught there as being so valuable that the system of irrigation with soap and water, according to the plan proposed by me, is to be given a trial of six months, in all cases of entero-colitis, including cholera, and at the end of the period of trial a final report will be made.

With this satisfactory outcome the system of treatment was tenderly committed by me into the hands of my foreign colleagues and my face was turned to Berlin and to Hamburg.

The epidemic at Hamburg, at the time I was admitted to the staff of physicians in the Epindorfer Krankenheitenhause, was on the decline. My admission to the staff of physicians was based upon the recommendation of Professor Virchow, seconded by Professor Guttmann, the intimate friend and colleague of Professor Koch. The experiments in the hospital at Hamburg were confined by me personally to two genuine cases of cholera, and the value of the treatment in these two cases was manifest to the cholera staff of physicians. It was a misfortune, and was deeply regretted by my eminent and distinguished friend, Professor Virchow, and others, that irrigation as a system of treatment had not been fully tried at the time of the height of the epidemic. It was the middle of August when I took my departure for Russia, and it was not until October 1st that I was able to visit Hamburg. My stay in the hospital at Hamburg lasted two weeks. I waited until the epidemic had ended, then went to Berlin and laid the facts before Professor Virchow and other medical gentlemen. Professor Virchow openly and freely commended the work that had been done, and presented his written congratulations to me, and otherwise treated me with affectionate regard.

I will state in this connection that the question of the etiology and spread of cholera and the value of quarantine measures and regulations is reserved by me for consideration at another time.

The value of my personal experiments in Europe during the epidemic of cholera of 1892 consists of the following conclusions:

1. Cholera is a disease which attacks the poor and the working classes.

2. The disease seldom affects the middle and the higher classes of society.

3. It is a disease which is transmitted by the discharges from the bowels and carried in particles of food and drink and on the soiled clothing of cholera patients.

4. It selects persons whose nutrition and nutritive organs are defective.

5. It has an especial affinity for the classes who live in the midst of and partake of filthy habits, and most especially for the intemperate and vicious classes.

6. The middle and higher classes of society are practically exempt from the invasion of cholera, and the fear and fright in which these classes indulge is without foundation.

7. The source of the infection and its method of transportation is not satisfactorily understood.

8. There are strong reasons for believing that cholera is spread by intercourse through travellers, and on the other hand there are strong reasons for believing that it is not so carried.

9. The scientific authorities of Europe are by no means agreed as to the exact manner of propagation of cholera.

10. The rated mortality of cholera in Europe in 1892 has not been materially different from the death rate of other epidemics during this century; the death rate has averaged very nearly fifty per cent.

11. Upon a review of the systems of treatment in Europe the rate of mortality does not show that medical science has been able by its scientific attainments to reduce the rate of mortality.

12. It is my belief, based upon my personal experiments, that irrigation as a system of treatment of cholera promises splendid results, and that if cholera cases could be treated early, by the system of irrigation, it would be reasonable to expect recovery, but in cases where the blood is already toxic it is not reasonable to expect recovery by any medical treatment.

13. It is my recommendation that in times of cholera suitable places be provided where the sick can be taken and treated by irrigation, without loss of time.

14. I would recommend that the poor and working classes especially be instructed in times of cholera, upon the recognition of any looseness of the bowels, to proceed at once to the nearest station which is properly provided with an irrigation apparatus, to be treated by physicians selected and paid by the city.

15. Should an epidemic of cholera prevail during some future time I would earnestly ask the co-operation of my colleagues to the end of further trials of irrigation as a reasonable and promising system for early treatment of cholera.

125 STATE STREET, CHICAGO, ILL.

Cholera in Hamburg.—The official reports state that there were about eighteen thousand cases of cholera during the recent epidemic in Hamburg.

DAYTIME ENURESIS IN CHILDREN.[1]

By JOSEPH B. BISSELL, M.D.,

NEW YORK.

INCONTINENCE of urine in children during the daytime only is not a very frequent occurrence. I have met quite a number of cases in both sexes in the past few years. They can for the most part be classified into three sets.

The first and least common form of the daytime incontinence is that due to some local disturbance or irritation, as phimosis, worms in the vulva, vagina, or rectum, inflammation of bladder and urethra, stone, growths in the bladder, etc. The most frequent, as well as the most intractable of these cases are not the result of local irritations or lesions, but due to some constitutional or general cause. The two other classes are very opposite in every other respect, except as to their incontinence. To the second class belong the bright, cheerful, and for the most part intellectually over developed children, excitable and mentally hypersensitive, active, playful, and happy in their disposition. The third group of cases are dull, stupid, and slow in mind and muscles. Their general condition may be either poorly nourished, anæmic, and feeble, or simply phlegmatic, with all the muscular development in first-class order, excepting only neck of the bladder. These latter cases are hard to understand. It is easy to explain the enuresis when there is general muscular debility, and the incontinence is only one in a train of symptoms following insufficient muscular development. Incontinence often persists after treatment has relieved the general health. Such cases are mostly night incontinence, and do not come into the scope of this short paper.

A general dyscrasia, such as rickets or scrofula, is not nearly so productive of enuresis as is commonly supposed. Mouth-breathing children are said to be more subject to it than others. I have met with several cases in the early stage of Pott's disease. After the incontinence has continued for some time the bladder is very likely to be very much contracted, or over-distended, and thus a result now becomes a cause of the difficulty, so that after the origin of the trouble has been removed we have still to treat a secondary cause, which is often more troublesome and takes longer to relieve than the primary one.

Polyuria is more apt to be a cause of night-incontinence, but when this is due to some lesion of a nerve-centre incontinence during the day is a frequent result. I have seen cases of daytime enuresis due to diabetes, and to polyuria from other causes. Epilepsy in its milder forms may be first noticed in an intractable incontinence.

The treatment of the first class of these cases is very simple in theory. Find and relieve the cause, and then, if necessary, go on and treat the condition which has been left by the incontinence.

The second class, those who are active, spirited children, is most troublesome to treat and difficult to cure. The worst type of this variety is seen in little girls who are at school, ambitious, striving, and active mentally. All the blood in their little bodies is driven to their brain by pushing teachers or ill-advised parents. The muscles are weak, the general body-condition poor and anæmic, and incontinence is frequent. This escape of urine may occur while sitting at their desks, while at their lessons, at recitation, or in the excitement of the play-hours. Sensitive in proportion to their highly developed brain and nervous system this is a great mortification to them. It depresses their minds and they may be reduced almost to melancholia by their trouble. Treatment of such cases requires the utmost tact and judgment. The first thing to do is to put aside the books and turn their minds and brains from marks and prizes to thoughts that are healthier and less stimulating. A course of treatment which develops muscle and builds up the blood is indicated, a nutritious and easily digested diet, stimulation of the muscles and skin by massage, sea-bathing, alcohol sponge-baths, friction of the skin by a coarse towel, etc. Girls from six to twelve years of age or over are most intractable to treatment, and often there is no use expecting to get much relief until lessons and books are absolutely prohibited, and outdoor exercises and air take their place. Among drugs the principal indication is, first, general tonics, as for instance syr. ferri iodidi, syr. hypophos. with nuc. vomicæ; cod-liver oil, tonic doses of quinine, and arsenic for the bodily condition. The best drug for the local effect on the bladder-muscles is belladonna, but it must be given until dilatation of the pupil to a considerable extent is obtained; the effect of this drug must be carefully watched and the patient given a good deal of attention. Strychnine is a drug of value in these cases, for its general effect as well as for its power over the sphincter vesicæ. A suppository containing one-quarter grain of nux vomica introduced three or four times daily into the rectum has had a very good result. Ergot, internally, combined with belladonna or strychnine, answers the indications. Rhus tox., in repeated doses of a quarter of a grain of the powdered leaves, is said to be very efficacious. The electrical current has been recommended very highly by German authors for this trouble. It is, of course, a powerful local stimulant. One electrode is applied to the perineum, the other to the hypogastrium or lumbar region. I hesitate about using instruments in the bladder and urethra unless there is positive evidence of bladder or urethral disease or of foreign body.

Yet the skilful and careful introduction in a boy of a steel sound large enough to dilate the deep urethra and distend the neck of the bladder will often assist greatly in the cure of incontinence. Ordinarily, and in the ordinary way, the introduction of a sound or the use of deep injections is brutal, and likely to do a great deal of harm, if it fortunately does not set up a cystitis or urethritis which may be very difficult to cure. The introduction of a sound when necessary may have to be done under ether or chloroform.

The third class of cases, where the children have all the muscles active and healthy except those of the bladder, are most puzzling. Any probable tendency to, or, a constitutional disease is either to be excluded or treated. Very often these patients are troubled with no other ailments but this one. It may have begun as a nocturnal enuresis and continued as daytime incontinence. The sphincters of the rectum are often irritable and untrustworthy, complicating the bladder trouble.

The remedies mentioned above are also available in this class. It may be that, following a long-continued enuresis from local or other long-since removed cause, the bladder has become contracted or contractured. If so, treatment of such a case will be long and tedious, and cure will depend on appreciation of the physical condition, the internal remedies above-mentioned, and the patience of the surgeon and the patient. I have never seen good results obtained in these or similar contracted bladders by forcible or gradual distention by means of hypostatic pressure.

The muscles of the bladder, acting very like muscles elsewhere in the body, become strengthened and developed by exercise. Forcible distention is a dangerous and decidedly unsafe method.

In those patients where all other methods have produced little result, and where the bladder is not contracted, continued washing of the bladder twice daily with a simple salt solution will sometimes restore to a certain degree, if not completely, the tonicity of the vesical muscles, and bring about a cure. This measure is not always practical, and is attended with considerable risk, which may be reduced to a minimum, however, by a skilful surgeon, with clean catheters and hands and a tractable patient.

Occasionally these cases get well spontaneously, especially as they reach the period of puberty, at which time the genito-urinary system undergoes rapid changes in its development.

AN IMPROVED METHOD OF PHOTO-MICROGRAPHY OF BACTERIA, AND OTHER MICRO-ORGANISMS.

Methods of Application and Analysis.

By ROBERT M. FULLER, M.D.,

FORMERLY LECTURER ON DERMATOLOGY, UNIVERSITY MEDICAL COLLEGE, NEW YORK.

The constant improvement in the art of photography, and its applicability in demonstrating the results of microscopic investigation of bacteria and other micro-organisms, makes it certain that, at an earlier day than investigators hoped, many of the now hidden mysteries of the animal, vegetable, and mineral kingdoms will be clearly unfolded to the inquiring mind of man. What are now, at best, only matters of conjecture, will be made as plain to the understanding as the most ordinary objects with which he is familiar. In other words, he will be able, by the combined aid of the camera and the microscope, to analyze the structure and life history of bacteria, and other micro-organisms, as readily as he may now view the process of manufacture of a needle or a pin.

That this is the future of scientific photo-micrography is evident to all advanced investigators in those special lines of research that demand continuous amplification of objects in order to analyze their minutest structural characteristics.

The possibilities of this style of scientific demonstration were first made apparent to the writer as far back as 1865, when in the United States Army Hospital, in Albany, N. Y., he found it practicable, through a series of experiments with the camera and microscope, to photograph various class-objects, by sunlight, with any desired enlargement. For example, the octohedral structure of the crystals of arsenious acid was shown clearly on the ground glass, despite the supposed hindrance to such photography caused by the refraction of light by the crystal. It was discovered then that there was none of the supposed blurring of the negative by refraction, but that the crystalline form was perfectly reproduced on the glass.

These arsenic exhibits were made at the time with the view of their utility as additional evidence in toxicological cases, supplementing the work of the analyst. These photo-micrographs of arsenious acid were afterward introduced as evidence in a case of poisoning brought before the Court of Oyer and Terminer, at Troy, N. Y., November 29, 1865, and were reported at that time to be the first application of photo-micrography to toxicology.

The various test objects embraced in these experiments were specimens in histology, pathology, entomology, crystallography, together with exhibits of vegetable tissue, diatoms, fosil radiolaria, urinary deposits, etc.

These slides and photographs, together with photographs of the apparatus with which they were made, are still preserved by the writer, the photographs having been exhibited by the President of the New York Academy of Medicine (Dr. E. R. Peaslee) at the stated meeting held March 22, 1871.[1]

The apparatus itself was similar to that by which the results obtained in 1891–92, hereafter described, with the exception of one of Lerebour's largest solar microscopes, owned by the Albany Academy and loaned me for this work. In my later outfit this has been supplanted by modern microscopes and objectives by Ross, Zeiss, and Leitz.

The experiments made since April, 1891, with this improved apparatus, have proved that a satisfactory negative made with sunlight may be successfully enlarged, and the sharpness and clearness of outline retained, until the very minutest detail of a micro-organism or other similarly minute object, is brought out with perfect clearness in the glass, positive or negative.

The usual magnification shown in photo-micrographs is between 1,000 and 10,000 diameters. In the experiments alluded to it has been found possible to reach and pass the point of 700,000 diameters of enlargement, still preserving the essential clearness of outline and amplification of detail.

This steady increase of enlargement from the ordinary enlargement is obtained by a series of threefold enlargements, that is to say, some interesting detail of the object under investigation is steadily reproduced, and enlarged threefold at each successive reproduction. Prints of each of these series of plates, positive and negative, were prepared and carefully compared, to make it plain that no defect of development had marred the work of enlargement.

Comparison of the positive and negative prints from the glass negatives and positives, indicated that what was obscured in the positive was made clear in the negative, and *vice versa*.

Three hundred photo-micrographs in series were made during these experiments, partly for the purpose of scientific investigation in certain lines, and also to test the possible limit of the process of enlargement. It was the discovery of the unexpected extent to which enlargement could be carried that indicated the near approach of the time when nature's secrets would be laid bare to the eye of the microscopist. Objects were selected which were certain to test the accuracy of the process of enlargement and reveal any distortion of outline, such as the diatom pleurosigma angulatum, etc. In pleurosigma angulatum, the work was rewarded by the discovery of a probable solution of certain points of structure which have been the subject of dispute between scientists.

The series of photo-micrographs included the following bacteria: spirillum cholerae asiaticæ, pure culture; spirillum undula; spirillum rubrum; bacillus leprae, bacillus typhosus; bacillus tetanus; bacillus tuberculosis, in pure culture, in sputum, in giant cells of human liver; bacillus anthracis, pure culture; bacillus subtilis; bacillus concentricus; bacillus megaterium; bacillus violaceus; gonococcus, micrococcus rosaceus; streptococcus; sarcina lutea, bacillus yanogenus; bacillus alvei. Also torula rosaceus, torula alba, actinomyces. Similar methods were pursued with several species of parasites, diatoms, etc.

The original incentive of these experiments was the possibility held out by the earlier results, of ascertaining if there was not a relation existing between a certain micro organism found on a negative of bacillus tuberculosis to the bacillus tuberculosis and other bacteria.

The negative was made on April 29, 1891; and the micro-organism was first noticed at the time that I was examining the negative, while still wet, with a hand-magnifier. The object appeared of peculiar outline, and perfect in form; about the size of three small pin heads placed in a row, and connected by a very fine hair-like line or filament. The upper one was slightly larger than the other two, which were about alike in outline. The larger was of similar size to the bulb-end of any of the bacilli on the negative. It excited curiosity, and suggested the possibility of being a rudimentary form of the bacilli in the negative.

Subsequently, from time to time, enlargements were most carefully made, and each enlargement brought out more and more details of perfect organization of the micro-organism. Amplification was carried up to the point of about 120,000 diameters, and unblurred detail still retained. This experiment resulted in a very clear and most interesting demonstration of a fully germinated spore, and this spore had thrown off filaments in different directions. Two of these filaments had two pod-shaped appendages each, and each contained nuclei. These spores, constantly enlarging, growing more detailed in structure as each reproduction was made, perhaps furnish an explanation of the mysterious growth of this group of bacteria.

Varieties of the bacillus tuber were subjected to the same process, and many interesting details of structure were developed.

[1] See Transactions of the New York Academy of Medicine, New Series, vol. i., part 1, page 3.

A photograph of spirillum undula was next subjected to the same process of enlargement, the reproduction being made from a negative made by sunlight.

Its distinctive cellular structure was shown, and full details of a novel and complicated system of spore germination were brought into view. It required very many photographs to follow out the different details of this germination, at so high an amplification as was necessary to produce the revelation of the system, the amplification in this case being as much as 70 000 diameters.

Several series of photo-micrographs were made of spirillum choleræ asiaticæ, in which certain details shown on one plate were carried up to a very high amplification. In one case, a print from a glass positive showed the general external appearance of the fleecy envelope, a flocculent spirillum, and also an aperture in the cell wall, sufficiently large to receive or expel a spore, several of which spores were shown in the photo micrograph. Another photo-micrograph produced two straight bacilli with an apparent connecting filament of very delicate cellular structure. Bacillus anthracis, similarly enlarged, produced in one photo-micrograph, made by strong sunlight, two highly refractive spores within each bacillus; most of the spores were round, but some were slightly oval.

While photographing gonococcus, an instructive picture was produced, showing the peculiar distribution and growth of this bacterium within each pus cell, as well as free gonococci ranged in pairs and singly within and between the cells. Bacillus leprae was also similarly investigated.

These experiments of the writer are made public at this time simply to indicate that the process by which they were made possible is one that will enable the scientific investigator to carry on a systematic and thorough investigation of bacteria and other microscopic objects, and thus obtain the information which is essential to their intelligent analysis and classification.

It is a method which promises to afford a correct solution to many of the problems in pathology and kindred research, which are yet matters mainly of conjecture rather than absolute knowledge; and, as has before been intimated, it seems to point clearly to that time when the profession will no longer have to conjecture, because the straight road will be opened to positive scientific knowledge.

136 West Forty-second Street.

A NEW METHOD OF CHECKING BLEEDING AFTER TONSILLOTOMY.

By ROBERT H. M. DAWBARN, M.D.,

PROFESSOR OF OPERATIVE SURGERY AND SURGICAL ANATOMY, NEW YORK POLYCLINIC.

A year or so ago I read a paper, written by Professor Delavan, of this city, upon the subject of tonsillar hemorrhage. In this article he has collected and discusses a very considerable number of expedients for governing the bleeding in this complication.

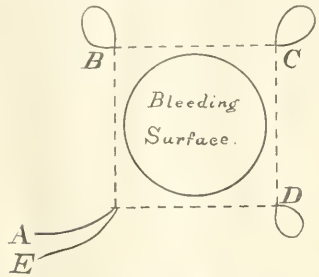
I was surprised not to find mentioned therein a method which I have taught my classes in operative surgery for several years past, and which seems unquestionably prompt, efficient, and easy of application; and is, furthermore, in my judgment, practically the best and wisest of the mechanical plans with which I am acquainted.

Although the expedient—which is presently to be explained, with a diagram—was of my own devising, yet it seems so self-evidently the thing to do that I took for granted the assumption that others must also have thought of the method and published it long ago.

Since reading Professor Delavan's paper, however, I have made some inquiries, and not finding the plan mentioned in any book at hand, Dr. Otto J. Müller, of 206 East 104th Street, this city, has recently obliged me by spending a day in the Academy of Medicine Library, looking up this question in English, German, and French literature. He states that he finds no mention of the plan which I am about to detail.

Briefly, it consists in surrounding the bleeding surface with a stout purse-string ligature, of silk or catgut, which when tightened is entirely hidden in the tissues about the tonsillar stump.

The surgeon selects a large needle, preferably semicircular in shape, and a needle-holder. The mouth is held open by a cork between the back teeth. Four stitches are now introduced, as per diagram. Less than two minutes is needed for this.



When the free ends, *A* and *E*, are drawn upon, the loops *B*, *C*, *D* of course disappear. The ligature is now tied tightly enough to stop bleeding, and the ends cut moderately short. The thread may either be left to slough out, or, and probably preferably, may be cut and removed in twenty-four to thirty-six hours.

As to the distance to which the needle penetrates, the two transverse strokes may enter to about one quarter inch in depth. The two vertical ones, running parallel with the carotids, could, if desired, probably be passed with safety rather more deeply; though there would seem to be no special advantage in this.

It is not necessary to include the pillars of the fauces in the grasp of the thread. The two vertically placed stitches run, of course, very near the pillars, but not really in their substance.

Regarding the source of hemorrhage after tonsillotomy, of one thing we can be certain, namely, that it never comes from either of the carotids. The external and internal carotids are very nearly equidistant from the tonsil, and behind it; the nearer, the internal, being rather more than half an inch away (1.5 ctm.); the external being, say, three-quarters of an inch (2 ctm.). If a tonsillotome be used, cutting either of these vessels is a mechanical impossibility.

At least six arteries supply the tonsil; all being branches, indirectly, of the external carotid. Of these the largest, as a rule, are from the ascending pharyngeal, and the ascending palatine.

Fatal bleeding from tonsillotomy is practically unknown. But bleeding to the verge of syncope, long continued, and severe enough to alarm most seriously the relatives and friends, if not the doctor—this is not so rare by any means. In such cases (in addition to nearly a dozen lesser mechanical devices) even ligation of one or another of the carotids has been advised, and actually practised; although of these vessels, tying the external carotid alone would seem rational; and that, too, only at a point between its first two branches—the superior laryngeal and the ascending pharyngeal.

However, with such a certain, safe, and easy device at hand as that which has herein been described, so severe a measure as cutting down and ligating a carotid can never be needed. Indeed, it would seem wisest to use the buried tonsillar ligature without waiting and wasting time and blood while trying less sure plans.

The nearest approach to this idea which the writer has anywhere found is a method suggested by Dr. E. W.

Clark, of New York, who has run two large needles through the bleeding base, and leaving these in place, wrapped a ligature firmly around them. Manifestly, even if this were equally as certain in effect, it would be quite as difficult to do as the writer's device, and must be much more annoying to the patient while in position. Indeed, the side of the tongue would be likely to be lacerated against the sharp needle-ends unless in some way these were covered.

The suggestion has also been made to seize with a volsellum forceps the bleeding surface, and drawing firmly upon it, tie a ligature about it. I have in one instance tried this, and found the ligature repeatedly slipping off in spite of my best efforts. Indeed, as there is nothing like a stump or pedicle left (if the tonsillotomy has been properly performed), such slipping is almost unavoidable.

I only mention this latter plan as being the other of the two which remotely resemble the method upon which this paper has been written.

105 West Seventy-fourth Street, New York.

CLINICAL OBSERVATIONS ON EUROPHEN.

By WILLIAM S. GOTTHEIL, M.D.,

Dermatologist to the Northwestern Dispensary, New York.

Many attempts have recently been made to find a substitute for iodoform which shall possess its valuable qualities without its irritant and poisonous effects. Of the various iodine derivatives that we have lately received, iodol, soziodol, dermatol, and aristol are the best known. But none of them seem to attain the object sought as well as europhen. Solubility, bactericide action, absence of poisonous absorption, absence of odor—in one or more of these properties the members of the first series are imperfect; but europhen shows all the desirable qualities.

Europhen is isobutyloxthocresoliodide, a stable iodine compound, which, under the influence of certain conditions, and especially when exposed to the action of the fluids, normal and pathological, of the organism, slowly liberates free iodine. It is an amorphous yellow powder, and contains 27.6 per cent. of iodine. It has a faint and pleasant aromatic odor, readily disguised if necessary. It is easily soluble in alcohol and ether, and mixes well with oils, fats, lanoline, talcum, and flexible collodion. It is insoluble in water and glycerine, and must not be used with preparations containing starch, on account of the iodine set free.

Europhen is anti bacterial in the same way that iodoform is, *i.e.*, it renders the medium in which it is present unsuitable for the growth of microbes. Siebel has proved that the two drugs are about equal in power. But it possesses the following advantages over the latter drug: it is almost odorless; it is non poisonous; it is one-fifth the weight of iodoform, and hence can be made to cover a much larger surface; it is more soluble; and it does not tend to cake.

Europhen has been used with great success as a dressing for wounds, in ulcerative nasal and laryngeal diseases, and in ulcerative syphilitic and chancroidal affections. During the past spring I have had some considerable experience with it in various diseases of the cutaneous system. The drug was used as an ointment with lard or vaseline, in strengths of half a drachm to a drachm and a half to the ounce; in olive oil half a drachm to a drachm to the ounce; and pure as a dusting powder.

I append a brief account of these cases.

Case I.—S. A——, female, aged ten, February 17, 1892. Diagnosis: Trichophytosis capitis. Single patch of half-dollar size, of five months' duration. ℞. Ungt. Europhen, ʒ j. to ʒ j., b. d.

March 28th.—Patch larger. ℞. Ungt. Europhen, ʒ j. to ʒ j.

April 20th.—Patch reddened; has not increased in size. Frayed hairs beginning to grow.

Patient withdrew from observation.

Case II.—H. W——, female, aged thirty-four, March 11, 1892. Diagnosis: Syphilis, tertiary; large papulo-tubercular serpiginous syphiloderm of cheek; rupia of arm; cachexia syphilitica, etc. ℞. Ungt. Europhen, ʒ ss. to ʒ j., and tonics.

March 16th.—Very much better; papules flattening; cicatrization beginning.

April 8th.—Splendid result; ulcerations have all healed under ointment; no internal treatment save mist. ferri et nuc. vom.

Discharged cured.

Case III.—A. F——, male, aged thirty-nine, March 21, 1892. Diagnosis: Papular eczema of legs. Ten days' duration; itching intense; skin torn by finger-nails. ℞. Ungt. Europhen, ʒ ss. to ʒ j.

March 23d.—Feels better. Less itching. Continue treatment.

March 28th.—Practically well; redness and irritation gone.

Discharged cured.

Case IV.—M. B——, female, aged forty-six, March 21, 1892. Diagnosis: Squamous eczema of right leg; parenchymatous dermatitis of left leg. The eczema is of long standing; the dermatitis is recent and progressing. ℞. Ungt. Europhen, ʒ ss. to ʒ j to both.

March 30th.—Both legs, but especially the eczema, improved. Continue treatment.

April 13th.—Both legs cured; excellent result.

Discharged cured.

Case V.—K. M——, female, aged forty-five, March 23, 1892. Diagnosis: Parenchymatous dermatitis of leg; ulcus cruris. Much pain. ℞. Ungt. Europhen, ʒ ss. to ʒ j.

March 25th.—Salve did patient good; ulcer contracting; less pain. Continue treatment.

April 4th.—Ulcer in statu quo; much discharge; abundant florid granulations.

Continue treatment.

April 11th.—Improving again. Continue treatment.

Patient withdrew from observation.

Case VI.—H. M——, female, aged fifty, March 11, 1892. Diagnosis: Eczema cruris, acute; Eczema seborrhoicum nasi. ℞. Ungt. Europhen, ʒ ss. to ʒ j. to both.

March 25th.—Worse; ointment "pierced" her leg. The eczema seborrhoicum has developed into an erythematous eczema of the face.

Europhen stopped, and other treatment instituted.

Case VII.—K. B——, female, aged thirty-four, March 25, 1892. Diagnosis: Eczema palmarum. Very bad. ℞. Europhen, ʒ ss.; ol. olivæ, ʒ ij.

April 10th.—Better. Continue treatment.

Patient withdrew from observation.

Case VIII.—A. M——, male, aged thirty-three, March 27, 1892. Diagnosis: Psoriasis vulgaris. Large thick patches on elbows and knees; a few guttate new ones on trunk. ℞. Europhen, ʒ j.; ol. olivæ, ʒ j.; soaked compresses to be applied to anterior surfaces of joints.

April 5th.—Scales gone; looks well. Continue treatment.

April 17th.—Patches on joints cured. Patient put on sol. Fowleri and iron for the general psoriasis.

Case IX.—J. H——, male, aged forty eight, March 4, 1892. Diagnosis: Psoriasis guttata universalis. Old case, recurs at least twice a year for the last ten years. ℞. Ungt. Europhen, five per cent., to arms only. Placebo internally.

March 25th.—Not much effect. Patient probably does not apply ointment thoroughly. Europhen stopped. ℞. Sol. Fowleri internally.

Case X.—J. C——, male, aged thirty-eight, February 29, 1892. Diagnosis: Folliculitis decalvans, limited to both knees. A chronic follicular and perifollicular pustular eruption of four months' duration. Cause unknown. ℞. Ungt. Europhen, ʒ ss. to ʒ j.

March 25th.—Ointment did some good. Most of the

papules have disappeared, the pustules have gone. Continue treatment.

April 4th —A large new crop of papulo-pustules in the last few days. Ointment pains him very much.

Treatment changed.

Case XI.—K. R——, female, aged fifty-four, March 30, 1892. Diagnosis: Rosacea, with some acne. Three months' duration. Plethoric habit; bowels costive. ℞. Mist. rhei et sod. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

April 15th.—Considerable improvement. Acne papules gone. Continue treatment.

Patient withdrew from observation.

Case XII.—A. K——, male, aged forty-seven, March 11, 1892. Diagnosis: Parenchymatous dermatitis and ulcus cruris. Eight months' duration. Ulcer indolent and dry. ℞. Europhen, ʒ j.; ol. olivæ, ℥ iv.

March 14th —More pain than before. The oil hurts for an hour after each application. ℞. Europhen, ʒ ss.; ol. olivæ, ℥ iv.

March 24th.—Ulcer in same condition, sluggish and dry

Treatment changed.

Case XIII.—C. B——, male, aged thirty-seven, March 11, 1892. Diagnosis: Papular eczema of legs. Both affected from knees down. ℞. Ungt. Europhen, two per cent.

March 25th.—Better; less itching. Papules fading.

Patient withdrew from observation.

Case XIV.—M. M——, female, aged eleven, March 11, 1892. Diagnosis: Psoriasis guttata, general. ℞. Ungt. Europhen, two per cent. to arms. Placebo internally.

March 23d.—Arms much better. Papules quite pale; scaling less; marked contrast to rest of body; itching less. Continue, and use ointment to rest of body—including face and head.

March 30th.—Improvement continues. Continue treatment.

April 6th.—Arms nearly well. Eruption over whole body very much better.

April 20th.—Arms clear; rest of body nearly well; face clear; no irritation; no conjunctivitis; a few scales on knees and back. Continue treatment.

April 27th.—Eruption gone.

Discharged cured.

Case XV.—K. McB——, female, aged thirteen, March 11, 1892. Diagnosis: Psoriasis universalis. Six years' standing. ℞. Ungt. Europhen, two per cent. to entire body.

March 20, 1892.—Improvement. Less scaling. Continue treatment.

Patient withdrew from observation. Improved.

Case XVI.—B. W——, female, aged seventy-two, March 14, 1892. Diagnosis: Pruritus senilis. Very bad case; cannot sleep at all; has lost weight and strength rapidly of late.

March 25th.—Various treatment, internal and local, has been tried without rendering the patient's condition any better. ℞. Ungt. Europhen, ʒ j. to ℥ j.

April 4th.—Salve did some good; itching less; rests better. Continue treatment.

Patient withdrew from observation.

Case XVII.—M. S——, female, aged thirty, March 21, 1892. Diagnosis: Eczema seborrhoicum, cheek and nose. Marked case. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

April 1st.—Face better; scaling gone; redness less.

Patient withdrew from observation.

Case XVIII.—A. D——, male, aged thirty, March 19, 1892. Diagnosis: Tubercular-ulcerative syphiloderm. Groups upon forearms and buttocks; ulceration rapidly progressive; scars of past destructive specific ulceration on various parts of skin. No history. ℞. Europhen, ʒ ss.; ol. olivæ, ℥ j., to be freely applied.

April 1st.—Ulceration stopped; papules flattening. Continue treatment.

April 10th.—Ulceration stopped; tubercles fast disappearing. Patient complains greatly of nocturnal cephalalgia and rheumatism. ℞. Mist. biniocidie, etc.

Further treatment was constitutional.

Case XIX.—A. C——, female, aged eleven, March 25, 1892. Diagnosis: Eczema seborrhoicum facei. Two months' duration. Slight scaling; little itchiness; nose, cheeks, and chin involved. Marked case. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

March 30th.—Excellent result. Face well.

Discharged cured.

Case XX.—C. T——, male, aged fifty-three, March 14, 1892. Diagnosis: Parenchymatous dermatitis; ulcus cruris. ℞. Europhen, ʒ ss.; ol. olivæ, ℥ iv.

March 16th.—Slight pain from the oil. No change in disease. ℞. Europhen, ʒ j.; ol. olivæ, ℥ iv.

March 28th.—Ointment pains moderate. Sore not improved.

Treatment changed.

Case XXI.—P. K——, male, aged thirty-nine, March 21, 1892. Diagnosis: Eczema squamosum. Both legs. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

March 30th.—Salve does not pain; it eases the itching a little—that is all. Redness and scaling the same.

Treatment changed.

Case XXII.—M. D——, female, aged thirty-four, March 15, 1892. Diagnosis: Eczema seborrhoicum. Chin. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

March 28th.—Much improved. Continue treatment.

Patient not seen again.

Case XXIII.—J. McA——, female, aged fifty-six, March 21, 1892. Diagnosis: Parenchymatous dermatitis; ulcus cruris; eczema papulosum of arms. Skin of entire leg inflamed; ulcer unhealthy, covered with green slough. ℞. Europhen, ʒ ss.; ungt. simpl., ℥ j.

March 30th —Much better. Slough clearing off; healthy granulations appearing. Continue treatment.

April 4th.—Edges healing nicely; whole sore in better condition; can walk better. Continue treatment.

Patient disappeared.

Case XXIV.—J. L——, male, aged thirty-five, March 14, 1892. Diagnosis: Chromophytosis over chest. Marked case, three years old; spreading much in the last few months. ℞. Europhen, ʒ ss.; ungt. simple, ℥ ij.

March 18, 1892 —Eruption almost gone.

Patient withdrew from observation.

Case XXV.—E. J. L——, male, aged thirty-two, March 25, 1892. Diagnosis: Chromophytosis. Entire trunk covered. ℞. Europhen, ʒ ss.; ol. lini, ℥ j.; Freely applied.

April 10th.—Eruption much better; nearly well.

Patient disappeared

Case XXVI.—K. D——, female, aged fifteen, March 28, 1892. Diagnosis: Eczema seborrhoicum. Cheeks and nose in subacute stage. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

April 10th.—Almost well. Continue treatment.

Patient did not return.

Case XXVII.—W. W——, male, aged forty-two, March 25, 1892. Diagnosis: Keratosis pilaris, thighs and arms. "Nutmeg-grater" skin. Much itching. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

April 10th.—Itching less; skin smoother; papules less prominent. Continue treatment.

April 15th.—Improvement continues. Continue treatment.

Patient did not return.

Case XXVIII.—A. S——, female, aged sixteen, April 11, 1892. Diagnosis: Alopecia Areata. Three months' standing. ℞. Ungt. Europhen, ʒ j. to ℥ j., to be applied vigorously.

April 20th.—No extension of the Alopecia. Scalp not reddened. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

April 28th.—Scalp moderately sore. Continue treatment.

May 8th.—Apparent good effect. Free lanugo growth on bald spots. Continue treatment.

Patient not seen again.

CASE XXIX.—J. K——, male, aged seventy, April 20, 1892. Diagnosis: Parenchymatous Dermatitis; ulcus cruris. Ulcer of eight years standing, sluggish, immensely thickened edges, dirty green base, odor bad. ℞. Poultice.

May 2d.—Sloughs cleaned off; surface of ulcer smooth and shining; no attempt at granulation. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

May 6th.—Looks better. Very slight pain from salve. ℞. Ungt. Europhen, ʒ j. to ℥ j.

May 13th.—Much better. Suppurating freely; abundant granulations; margins covered with white pellicle; healing. Continue treatment.

May 18th.—Same condition. ℞. Ungt. Europhen, ʒ jss. to ℥ j.

June 3d.—Doing splendidly. Ulcer much contracted. Last note, made June 10th, showed steady improvement.

CASE XXX.—M. M——, female, aged eighteen, May 2, 1892. Diagnosis: Psoriasis Guttata. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

May 23d.—Scaling much less; better. Continue treatment.

Patient did not return.

CASE XXXI.—J. M——, female, aged forty, April 20, 1892. Diagnosis: Parenchymatous Dermatitis; ulcus cruris. Old case. ℞. Ungt. Europhen, ʒ j. to ℥ j.

April 25th.—Looks healthier. Continue treatment.

May 2d.—No marked change. Patient is careless, and does not dress ulcer properly.

May 13th.—Same. ℞. Ungt. Europhen, ʒ j. to ℥ j.

May 18th.—Patient complains much of pain from the salve. Ulcer covered with a green slough. Has not used the ointment, evidently.

Other treatment instituted.

CASE XXXII.—F. W——, female, aged thirty-three, colored, April 18, 1892. Diagnosis: Large ulcerative tertiary syphiloderm. Leg. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

May 13th.—Patient has used salve only. Ulcer is almost well. Continue treatment.

Patient was not seen again.

CASE XXXIII.—P. S——, male, aged twenty-nine, May 2, 1892. Diagnosis: Parenchymatous dermatitis; ulcus cruris. Some months' standing. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

May 6th.—No change. ℞. Ungt. Europhen, ʒ j. to ℥ j.

May 16th.—No better; salve hurts moderately. No result. Treatment changed.

CASE XXXIV.—E. M. G——, female, aged forty, May 20, 1892. Diagnosis: Tertiary tubercular ulcerating syphiloderm. One month. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

June 10th.—Doing very well; healing fast.

Patient did not return.

CASE XXXV.—M. C——, female, aged forty-six, May 27, 1892. Diagnosis: Acne indurata. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

June 6th.—No improvement at all.

Treatment changed.

CASE XXXVI.—T. T——, male, aged eight, June 1, 1892. Diagnosis: Trichophytosis corporis. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

June 3d.—Better; less redness; no extension. ℞. Ungt. Europhen, ʒ j. to ℥ j.

June 6th.—Well.

Discharged cured.

CASE XXXVII.—P. K——, male, aged nine, June 8, 1892. Diagnosis: Trichophytosis corporis. ℞. Ungt. Europhen, ʒ ss. to ℥ j.

June 10th.—Same.

June 15th.—Seems to be spreading. ℞. Ungt. Europhen, ʒ j to ℥ j.

June 19th.—Improvement. Continue treatment.

Patient did not return.

Summary.—The best results were obtained with the drug in tertiary syphilitic ulcerations. Out of four cases, three were rapidly cured, and one was much improved when lost sight of. Excellent results also were seen in chromophytosis (pityriasis versicolor), and trichophytosis corporis (tinea circinata) the two cases of each disease getting well quickly.

Ringworm of the head, on the other hand, as well as acne and folliculitis, were not affected. Pruritus senilis, alopecia areata, and keratosis pilaris showed benefit from the use of the drug, but not more than is usually obtainable by other means.

Of eczemas (seven cases) the more chronic varieties were improved and two cured; the acute varieties were not benefited; and on seborrhœal eczemas the effect was undecided. The drug deserves further trial in chronic cases of this malady.

In parenchymatous dermatitis with ulceration (seven cases), chronic cases, with sluggish ulcers and dead tissue were much benefited, though I have not recorded a single case as cured. The well known obstinacy of the malady, and the practical difficulties in the way of its ambulant treatment, fully account for this.

In all the five cases of psoriasis but one the improvement was marked. The result was fully as good as that obtained by the use of chrysarobin for the same length of time; over which drug europhen possesses great advantages in point of non-irritating and non-poisonous qualities.

Clinical Department.

RECORD OF NINE CASES OF GONORRHŒA SUCCESSFULLY TREATED WITH HYDROGEN PEROXIDE, UNDILUTED.

BY L. L. VON WEDEKIND, M.D.,

U. S. NAVY.

WITH a record of nine cases of gonorrhœa, treated in the earlier stages by injection of hydrogen peroxide, with uniformly good results, I feel that this method of treatment should become known, as it has, so far, benefited the patient, not only medicinally, but financially and socially.

Some months ago I was visited by a young man who came in a state of great mental excitement, and actually demanded that I cure him at once of an attack of gonorrhœa. His reason for being so abrupt and positive was, that he was in a few days to be married, the cards and consequent paraphernalia attending such an occasion had all been gone through with, and, as he said, "I must be married, and you must cure me."

The history of the case was as follows: At a farewell dinner given to bachelor friends six days before coming to see me, he partook not sparingly of wines, and after dinner and before going home, he met a lady acquaintance, and being still a bachelor, did as bachelors do. When I saw him, he complained of a burning sensation along the urethra during and after micturition, and had that morning noticed that the lips of the meatus were glued together, and concluded that the uneasy sensation about the parts foretold an approaching attack of gonorrhœa. Of this fact he was certain, as he had before suffered from the same disease, and knew well the symptoms. I have no doubt whatever that his diagnosis was correct.

After having obtained a full history of his case, I forced out whatever was in his urethra, and had it examined under the microscope by a competent observer, who, however, reported nothing specific, but requested some slides a few days later. These I promised him. Before hearing the results of the examination by my friend, however, I had to do something for my patient. He very

bravely declared that, rather than run any risk, he would find some pretext or other to postpone the ceremony. I told him to wait for twenty-four hours before deciding on anything, and at the end of that time I would give him my opinion as to whether or no I could help him. He was placed on rather large doses of acetate of potassium, and I told him to use as an injection, beginning at once, the undiluted solution of hydrogen peroxide, four or five times; to inject very thoroughly and to close the meatus after the syringe was withdrawn, the solution to be kept in place for at least five minutes after each injection, and to inject standing up, not restricting the bladder end of the urethra. He carried out my directions so thoroughly as to use twelve injections in the twenty-four hours, and twice as much of the internal remedy as I had ordered, but with very excellent results.

I saw him next day, and found that he had gotten rid of all his annoying symptoms, and I then suggested that if he could not find a very plausible excuse, why, to go ahead and get married, but in the meantime to continue treatment in a modified form. This he did, and was married a little less than a week after. I was much worried at the time, fearing a return of the disease, but nothing happened.

The seven cases following this were all treated in the same way, and in each the disease was aborted. None of these cases had developed the active inflammation to such an extent as to have much if any discharge, but all evinced symptoms indicating a commencing attack, and these symptoms are so well known to the initiated patient, that the correctness of their diagnosis of the case is almost beyond doubt.

The ninth case I treated at the Naval Hospital in Chelsea, Mass., but a few days ago. The patient's history is similar to the first case as regards the length of the period of incubation, six days. This is the first attack, and the patient stated that he did not know what was the matter. He was put on potassium acetate, twenty grains four times daily, and used hydrogen peroxide undiluted, ten-volume strength, five times in twenty-four hours, continuing the treatment for three days; he was also confined to his bed and placed on restricted diet. I personally supervised the use of the syringe in this case, and noticed that the escape of the solution, after being retained for five minutes, was as if it were shot out, gas and a frothy foam being mixed with it. But little pain was at first noticed, though it increased somewhat after the third injection. After the first day's treatment, however, the patient suffered but little discomfort when using the syringe.

I have used this solution in different stages of the disease, but have not found it to be much superior to the many others used, except in so much that it is less painful than many others (I have used it in one-half or one-quarter strength in the acute or later stages), and also that it is a most excellent cleansing agent. Cases that have been discharging more than two days I have been unable to abort.

The use of this drug in the early or incipient stage of gonorrhœa, I believe will cause the disease to remain a local trouble, prevent the absorption of the septic material—in other words, prevent gonorrhœal septicæmia by the removal of the hotbed of infection, as it is supposed to do in diphtheria.

Very probably, some will suggest the possibility, perhaps the probability, that none of these cases would have developed into a specific urethritis, if allowed to go on. Possibly they may be right. Nevertheless, by experience I have found that when the disease is once fairly started—in fact, when the discharge is more than two days old—the hydrogen peroxide will not abort the trouble, and also that it will allay all the prodromal signs and symptoms if used upon first noticing any manifestation of these.

To the "doubting ones" I would suggest that they call to mind that little story of "the barn door and the horse." To await an indisputable diagnosis by the microscope to the exclusion of the history, symptoms, and signs, is to allow the disease to run its course, for I do not believe that any germicide preparation will penetrate deeply enough to catch the gonococcus after it has passed into the deeper layers of the epithelium.

A SEVERE CASE OF SUPPURATIVE ADENITIS.

By FRANK A. BOTTOME, M.D.,

NEW YORK.

I was called in to see Margaret ——, aged sixty-two, servant, on August 1st, and found she had been suffering for three days with a sore throat, but had said nothing about it for fear of troubling her mistress.

Examination showed the left tonsil swollen and points of pus at the mouths of the follicles. These patches could be wiped off with bits of cotton without causing bleeding from the membrane beneath. The soft palate was swollen and uvula œdematous; the right tonsil was intact. Temperature, 102° F.

My diagnosis was follicular tonsillitis, and I ordered sod. bicarb. applied locally, and iron internally.

On the following day her condition was about the same, but on August 3d the right tonsil became involved. The swelling of both tonsils was now considerable, and the uvula was swollen and œdematic, so that it was very difficult for her to take either fluid food or medicine, the larger part being regurgitated through the nose.

On the following day the submaxillary glands were found enlarged and very tender on pressure. The difficulty of deglutition was even more marked, but the patient's pulse and general strength were remarkably good.

August 5th.—Her condition was even worse, owing to the involvement of the sublingual gland, which was so swollen as to push the tongue up against the roof of the mouth. At this time I found, situated on the floor of the mouth on the right side and extending along the inner gum to the middle line, a dark-grayish membrane and the attempt to lift this up caused the membrane beneath to bleed. I also found the post-cervical glands enlarged.

In the evening of August 5th, Dr. S. F. Morris was called in consultation, and after a careful examination we came to the conclusion that it was probably diphtheria, though the age of the patient was against such a diagnosis, as was the fact that there had been no previous case of diphtheria in the place. It was impossible at this time to see anything behind the tonsils and uvula, owing to the swelling and œdema.

To assist in clearing the doubt in diagnosis, I removed a portion of the membrane and sent it to Dr. F. Ferguson, of the New York Hospital, and in the meantime removed the patient, who was staying in a large summer boarding-house, to an isolated cottage near the ocean, where, under the care of a trained nurse, she could have better attention.

August 7th.—A large amount of pus was evacuated from the sublingual gland.

The following day the right tonsil broke and evacuated a quantity of pus. The left tonsil subsided by resolution, and the condition of the patient was very much improved, fluid food being readily taken. The submaxillary glands, especially the right, remained swollen, and notwithstanding they were poulticed continually, did not soften, nor could I detect the presence of pus on palpation.

August 10th.—The right tonsil, which after breaking had gone down nearly to normal size again, discharged a large quantity of pus, and at the same time a diminution took place in the size of the right submaxillary gland. From this time on convalescence was uninterrupted, and on August 16th the patient was able to go to her home, near New York City.

In the meantime Dr. Ferguson had made an examination of the specimen which I had sent him, and reported

that "sections through it failed to reveal any of the elements ordinarily found in diphtheritic membranes," but that it was "a necrotic mass without any structural arrangement;" also, "that bacteriological examination proved negative."

The case is interesting first, from the question of diagnosis. The membrane certainly resembled a diphtheritic membrane in its gross appearance, and the bleeding on attempting to remove it from the underlying tissues was characteristic, as was also the general involvement of the glandular structures in the vicinity. On the other hand, against such a diagnosis was the fact that there had been no case of diphtheria in the neighborhood for months previous, nor did any occur subsequently during my stay in the place, which was two months.

Secondly, if then it was a case of suppurative tonsillitis, or better, adenitis, involving as it did more than the tonsils, it is interesting from the fact that such an extensive suppurative process should occur without any apparent cause, such as diphtheria or scarlet fever, and also from the fact that the patient made a good recovery.

134 West 126th Street.

DIGITALIS IN PNEUMONIA.

Dr R. I. Bond, of Hartshorne, I. T., writes that he has never failed to obtain the desired result from the use of digitalis in pneumonia, if given after the following method:

"Begin with a medium dose, the fluid extract being my preference, and gradually increase until the pulse is reduced to a little below normal, then decrease until the normal pulsation returns and hold it at that until all expectoration subsides; then gradually decrease until the dose is so small that you can safely stop its administration, convalescence by this time being quite advanced. It will probably be asked what are its effects outside of those upon the heart. 1st, It is the only permanent antipyretic; 2d, the only reliable sedative; 3d, the only effectual means of rapidly controlling the flow of blood to the inflamed lung, hence it soon checks expectoration by rendering it unnecessary; and 4th, it has the diuretic effect which is needed in most cases of pneumonia. The dose is to be measured by the amount of obstruction in the circulation through the lung. I have found it necessary to increase the dose to fifteen drops of the fluid extract every four hours to control the heart's beat in adults where there was extensive obstruction in the lung. I have given to a child four years old four drops every three hours with nothing but the desired effect. This was in a case of capillary bronchitis, in which trouble it is quite as efficient as in pneumonia. A favorite combination is this:

℞. Aromatic spirits of ammonia..... ʒ ss.
Fluid extract of digitalis..... ʒ iiss.
Glycerine .... q. s. ad ʒ iv.

M S.: Teaspoonful every three or four hours, to be increased as the case may require.

VALUE OF THOROUGH VAGINAL TAMPONING IN PLACENTA PRÆVIA.

By JOSEPH S. HEALY, M.D.,
Assistant Laryngologist to Demilt Dispensary, New York City.

Placenta prævia, particularly in cases where it is of the complete variety, being one of the most formidable and dangerous abnormalities which can be encountered in obstetrical practice, anything written from personal experience, especially where the line of treatment adopted terminated in saving the patient, must be of value to the obstetrician. With this fact in view I shall, without further apology or preface, endeavor to give an accurate account of a case of complete placenta prævia which fell to my lot.

The patient was Mrs. D——, whose previous history is as follows: Her first pregnancy was attended with no unusual symptoms, labor was normal and terminated in the birth of a daughter, who is now living, aged seven years and seven months, and in good health.

About five years ago she became pregnant for the second time. In the fourth month of her second pregnancy she claims the membranes ruptured, causing a great discharge of water, and from that time on there was a constant leakage of water until the sixth month, at which period she aborted, giving birth to a living fœtus which lived six hours. Her family physician at that time had considerable difficulty in removing the placenta. The cause of the abortion I have been unable to learn.

In February of the present year she became pregnant for the third time. In the second month of her late pregnancy, at about what would have been her period of menstruation, she had a slight discharge of blood from the vagina. In the third month a similar discharge occurred. When this second hemorrhage began she consulted me, in order to ascertain whether she was pregnant or not. After making as thorough an examination as the existing circumstances would permit, I informed her that she was pregnant, and administered a uterine sedative which stopped the flow, and the pregnancy progressed with no further untoward symptoms until about the commencement of the seventh month, when the third hemorrhage occurred

Arriving at her bedside I found a slight hemorrhage existing, but unaccompanied by pain of any character. Examination disclosed no dilatation of the external os. There being no apparent cause for the flow, I at once suspected it to be a case of placenta prævia. I administered a uterine sedative, and as a precautionary measure tamponed the vagina and cautioned her to remain in bed under all circumstances. The next morning upon removing the tampons I found the hemorrhage had ceased, and but one of the three tampons inserted was blood-stained. After keeping her in bed for four days, during which time no further symptoms developed, I allowed her to get up, but cautioned her to do no housework.

In the eighth month, about the menstrual epoch, the hemorrhage again appeared, unaccompanied by pains, and examination revealed no dilatation of the os. Satisfied with the serious nature of the trouble which I had to contend with, I explained it to both the patient and her husband, at the same time informing them that the proper treatment would be to terminate her pregnancy; but at their urgent request I postponed active measures, and again administered a uterine sedative and ordered the patient to remain in bed, and in a few hours the hemorrhage ceased.

On October 20th a very profuse hemorrhage occurred; this time, however, accompanied with true labor pains. An examination showed the external os was beginning to dilate, but I was unable to pass the internal os. The patient being somewhat anæmic from loss of blood, I decided to tampon the vagina and cause the blood to dissect the placenta from the uterine walls. It required eighteen cotton tampons, each tampon as large as could be passed through an ordinary bivalve speculum, to completely fill the vagina and control the hemorrhage. After waiting about four hours, all labor pains having ceased, I removed the tampons and found the os fully dilated with a portion of the placenta presenting. Careful examination revealed a case of complete placenta prævia.

Sweeping my finger around inside the os as far as I could reach, I found, as anticipated, the placenta had been dissected from the uterine walls, but to what extent it was impossible to ascertain. I was about to push through the placenta and pull the feet down when I decided it would be safer to have assistance and administer chloroform. I sent for Dr. Thomas Darlington, and after consultation administered the chloroform, while he endeavored to push through the placenta. I say endeavored, because when he attempted to do so the placenta simply dropped off from its attachment to the uterus, demonstrating the fact that the tamponing had caused the blood

to dissect up the entire placenta, leaving it attached only by a rim so narrow that it gave way upon slight pressure.

Seizing the feet, which were near the os, he pulled them through into the vagina. At this stage his hands became so slippery that he was unable to draw the body down. My hands being dry, I seized the feet and drew the body down and out of the vagina; the uterus contracting strongly instantly expelled the placenta with absolutely no hemorrhage.

Notwithstanding all antiseptic precautionary measures, on the third day symptoms of septicæmia set in. On the fifth day the temperature was 103° F., with extreme tenderness of the uterus, accompanied by an extremely fetid discharge, which I successfully treated by curetting the uterus and using intra-uterine antiseptic douches freely.

The two cardinal points which I wish to draw attention to are: First. The treatment *par excellence* in placenta prævia, or suspected cases of the same, is thorough vaginal tamponing. Had I attempted rapid dilatation by the use of Barnes's bags or instrumental dilators the resulting hemorrhage would have been disastrous. Second. No physician should attempt to deliver in a case of placenta prævia without assistance. Should the placenta be adherent and the physician not succeed, owing to slippery hands or otherwise, in drawing the body of the child through the os, before he could dry his hands and again grasp the legs, the hemorrhage would, in all probability, cost the patient her life.

In conclusion, I will briefly mention that my last nine consecutive obstetrical cases were as follows: Five abortions ranging from four to seven months; one shoulder presentation; one hand and foot presentation; one case of puerperal eclampsia, and one complete placenta prævia.

2886 Bailey Avenue, Kingsbridge, New York City.

A STUDY OF THE RELATIONSHIP BETWEEN THE SPHINCTER OF O'BEIRNE AND THE VALVE OF BAUHIN IN THE FUNCTIONING OF THE LARGE INTESTINES.

By HENRY V. GRAY, M.D.,

Roanoke, Va.

The arguments and demonstrations so ably brought forward many years ago by O'Beirne, upon the constriction situated at the line of junction between the sigmoid flexure and rectum in defecation, have been neglected by our profession. His argument was to the effect that the rectum is contracted and contains neither gas nor fæces in ordinary conditions. That expulsion of fecal matters followed only after the rectum was distended, and that peculiar sensation for evacuant relief was established. O'Beirne demonstrated that at this intestinal junction before spoken of, the fecal matters are arrested and remain there for a definite period, when the constriction relaxes and the matters pass into the rectum. This being established as a physiological fact, he went further, to prove that the muscular fibres were truly sphinctal in their action. This led our anatomists to name this sphincter after its distinguished observer—sphincter of O'Beirne.

Promising this as a study, I shall feel myself especially honored to take up the scalpel handed me by the eminent observer, to find new fields of deduction.

I shall claim, in the beginning of this study, that the sphincter of O'Beirne has a powerful influence over the large intestines, and, indirectly, the small intestines are impressed. At the junction of small with large intestines, there is a valve, familiar to all of us, the ilio-cæcal or valve of Bauhin. This special anatomical region has lately been much talked over and experimented upon, on account of the little worm like process called vermiform appendix. It is subject to inflammation, from foreign substances getting into it, 1, because the ilio-cæcal valve has not performed properly its duty; 2, because the repository to its falsity attempts to conceal its ill gotten gains by confederating with its more unfortunate neighbor, the vermiform appendix—vulgarly spoken of as the "monkey tail." We know the repository of the ilio-cæcal valve is the cæcum, and that a valve likewise guards closely the entrance to the appendix. The cæcum is located immediately behind the anterior abdominal wall in the right iliac fossa, being retained in its position by a fold of the peritoneum. Both the large and small intestines have longitudinal muscular fibres to give strength and force to propulsion of contents. The former (large) division has its longitudinal fibres arranged in bundles, or "three flat longitudinal bands." We are told their anatomical arrangement is into anterior, posterior, and lateral. "These bands are nearly one half shorter than the other parts of the intestine, and serve to produce the sacculi which are characteristic of the cæcum and colon; accordingly, when they are dissected off the tube can be lengthened, and its sacculated character becomes lost." I will likewise add that this arrangement of the longitudinal bands gives to the colon a spiral action, which greatly promotes and multiplies its power for motion. The circular fibres are scattered around the colon in thin layers, having special thickness and power at distinct intervals. We are now anxious to find out what influence can the sphincter of O'Beirne have in the functioning of small and large intestines at this point.

The sphincter of O'Beirne is a retaining one, and is intended to act rhythmically with the associate parts. Ordinarily the fluid contents of the small intestines are emptied into the large intestines by the way of the valve of Bauhin, at some regular interval. The fecal matter is now in readiness to pass along the colonic conduit to its place of arrest at the sphincter of O'Beirne. Its advance is much slower in the colon than in the small intestines. Having observed closely the muscular distribution, the longitudinal fibres shorten to draw up the yet fluid matters, each sacculus of the ascending colon acting as so many basins; while the lower circular fibres contract, the upper relax, thus furnishing a threefold force to propulsion. Of course, as the fecal matters pass on to the other divisions of the colon, the watery portion is taken up, and the residue becomes more solid, until it reaches the sigmoid flexure. We have argued a purely normal conduit. We will now suppose that we have to deal with some morbid state.

The upper portion of the rectum, in front, is in relation with the posterior surface of the bladder in the male, and the posterior surface of the uterus and its appendages in the female. The middle and lower portions of the rectum are in relation, in front with the male bladder, vesiculæ seminales, and vasa deferentia, and with the prostate gland and membranous portion and bulb of urethra. In the female it is adherent to the posterior wall of the vagina, and the intervening space between it and the vagina. The latter space is the perineum. The reader will take notice that I am treading on strictly anatomical parts, and can, therefore, claim their strict attention and confidence. Once more. The pelvic portion of the sympathetic system of nerves converges and unites in front of the coccyx by means of a small ganglion—the ganglion impar. What more would you have me to produce to prove that a morbid state frequently attends this region, particularly the sphincter of O'Beirne, and its fatal and damaging influence; in fact, over the entire abdominal and pelvic circle? When this sphincter of O'Beirne becomes stiffened or relaxed, the same longitudinal fibres, from cæcum to rectum, become involved in the torpor; likewise the valve of Bauhin, until the healthy tone is lost. The liquid contents rush on rapidly to the relaxed sphincter, and meeting with no resistance, pass out before they have solidified. The fecal matter becomes, in fact, an irritant—no longer fit for use in the economy. This sphincter can likewise become relaxed, stupid, or otherwise deranged from many causes, none more so than intemperance in its widest sense, and epidemic causes. Again, it takes on spasmodic action from the same and other causes, until the most obstinate constipation and impac-

tion at some point may follow. Any irritation of the genito-urinary centre will most assuredly affect this sphincter. As I have spoken of the ganglion impar in this study, I will at present point to its healthful or baneful influence over this entire region; but it more especially presides over the internal sphincters of anus, uterine cervix, and bladder. It is a study within itself—I will therefore leave it for some future occasion. But little medical literature is at my disposal, if published, upon this important ganglion—the ganglion impar.

To fortify still further my position, I will ask you to take up the colon and its kindred parts, and liken it to a mechanical power and observe with a mechanical eye. Think of the colon as a piece of rubber hose, hang it that it may assume some shape, with valve and sphincter in their true relative positions, and operate the parts like the natural parts, and you will find it almost in the shape of a horse-shoe syphon, the sphincter of O'Beirne being lower than the inlet. This may be regarded as a bunglesome illustration, nevertheless it may help others to do better.

In conclusion I will consider one more point, and thus make practical my feeble effort.

A large majority of our physicians, in directing their patients to massage the abdominal walls just before going to stool, instruct them to "work over and around" the navel and right iliac region or cæcum, and to pass up and around the line of the colon to the left groin, and there stop. No instructions are given to massage this point. If O'Beirne's arguments and my deductions are correct, I take much pleasure in telling you to massage especially the sphincter of O'Beirne, and the sigmoid area. You will frequently be gratified to feel and hear the moving of the gases and fecal matter. You cannot force the colonic contents from cæcum to sigmoid flexure at once; it takes its own time, but you can persuade the sphincter of O'Beirne to relax and allow contents to pass into the rectal pouch, ready for commonsense defecation. Let me beg the profession not to deal harshly with this sphincter by meddlesome colonic irrigation. You can go a long way by persuasion and massage, provided the defect resides within the area of the sphincter of O'Beirne. The important relationship of this sphincter, together with the recto sigmoidal area, must have great significance in diseased states, if we will only mentally review each part, both in male and female patients, when they seek our aid in obtaining relief.

A CASE OF BILATERAL PARALYSIS OF THE ABDUCTORS OF THE VOCAL CORDS.

By CLINTON WAGNER, M.D.,

SENIOR SURGEON, METROPOLITAN THROAT HOSPITAL, NEW YORK.

BILATERAL paralysis of the abductors (crico-arytenoidei postici) of the vocal cords, is the most unusual of all the varieties of innervation which affect the larynx. When we consider the large number of specialists who are engaged in throat practice, in this country and in Europe, the number of cases placed on record appears surprisingly small; consequently, every case is invested with more or less interest to the profession, especially as the etiology of the condition cannot, in the majority of cases, be determined during the life of the patient.

We know that pressure upon both recurrents, by enlarged bronchial glands, a mediastinal tumor, an aneurism of the arch of the aorta, or the innominata involving the right subclavian, extra-tracheal pressure from an enlarged thyroid gland, are causes which may generally, but not invariably, be recognized during the life of the patient. If none of the causes above enumerated is present, then we are forced to conclude that the cause is central, even where there is no other evidence of cerebral disease.

This view, which is held by most writers on the subject, has been confirmed by the recent experiments of Felix Semon, in connection with Victor Horsley (*British Medical Journal*, December 21, 1889), who found a "proclivity of the abductors to fail in organic disease."

In order to prevent death from glottic spasm, tracheotomy should be performed without delay. If the patient objects to the operation, the great risk incurred of death by asphyxia should be fully explained to him; as a rule, consent will be given, after he has been made to appreciate the serious nature of his condition. If there is a history of syphilis, the proper treatment may be carried out after the introduction of the cannula. Electricity is of no avail in these cases, and if applied to the cords before tracheotomy has been performed, may bring about fatal spasm of the glottis.

The following well marked case is of interest, from the fact that the cause of the paralysis has not as yet been ascertained, and as showing the great improvement in the general condition of the patient after the operation of tracheotomy.

P——, aged forty-five, Irish, occupation, plasterer, was admitted into the Metropolitan Throat Hospital, October 3, 1892. He stated that about a year ago, after exposure, he caught a severe cold, which left him with impaired power to breathe freely; previously, he had never experienced any difficulty in breathing. About six months before entering the hospital he became worse, lost rapidly in flesh and strength, and was unable to work with regularity at his trade.

At the time of his admission into the hospital there was constant dyspnœa, especially well marked during inspiration, and upon making the slightest physical exertion, for instance on ascending stairs, it was greatly increased and became stridulous. Attacks of spasm of the glottis occurred nightly, and were becoming more frequent and more severe in character.

A laryngoscopic examination showed that the cords were fixed in the position of adduction, and upon inspiration the space between them did not exceed one-tenth of an inch; his voice, of course, was unimpaired; the cords appeared healthy and were not atrophied. A careful examination of the chest failed to discover evidence of aneurismal or other pressure upon the recurrents. About sixteen years ago, he had a gonorrhœal discharge and he thinks a chancre, but since then he has had no symptoms of syphilis. No result has followed antisyphilitic treatment, which has been thoroughly tried.

Tracheotomy was performed. Since the operation he has gained greatly in strength and about fifteen pounds in weight, he sleeps well, and has an excellent appetite. The position of the cords is unchanged.

65 WEST THIRTY-EIGHTH STREET.

THE TREATMENT OF DIPHTHERIA BY PYOKTANIN.

By LOUIS FISCHER, M.D.,

NEW YORK.

PYOKTANIN, or methyl-violet, as it is sometimes called, has been advocated for some time in the treatment of diphtheria. Recent contributions to medical literature have been made by Dr. Jaenicke, in *Therapeutische Monatshefte*, 7 Hefte, and since then by Dr. Taube, of Leipsic. It has been recommended not only in the treatment of diphtheria, but also in the treatment of scarlet fever, diphtheria, tonsillitis, and soor.

An elaborate article appeared in the *Deutsch. Med. Wochenschrift*, No. 38, by Dr. Taube, since which time I have used it in fifteen cases of diphtheria which I have not only clinically but bacteriologically proven to be true diphtheria. The method of applying it has been in the form of an aqueous ten per cent. solution directly to the affected parts by means of a glass rod (applicator), around which a pledget of cotton soaked in the solution was used. After each application the cotton was burned in order to avoid further infection. Five minutes before each application the child received a teaspoonful of bi-

carbonate of soda dissolved in a tablespoonful of water. The applications were made twice a day for three days, and no other treatment given. Some cases required its continuation five and six days, and one case still needs treatment—eleven days. Good wine, stimulation, and farinaceous diet were also used. The condition of the urine and the bacteriological results and post-mortem effects will be dealt with later. This is merely intended to be a preliminary announcement.

40 Rivington Street.]

Progress of Medical Science.

Pneumathæmia.—In an editorial article published in the *Medical News* we are informed that this name was coined by Cless to denote a condition in which air is present in the blood-vessels. In the medical literature of the past seventy years many cases are recorded in which the blood-vessels after death contained air or gas, which did not seem attributable to post-mortem decomposition. In some cases, especially in the course of surgical operations about the neck, death has been supposed to result from the entrance of air into the veins. Such cases have been the subject of much dispute. Experimental work has been done that proves that very large quantities of air must enter the vessels for death to ensue; thus Nysten found the lethal amount introduced into the jugular veins of dogs to vary between 40 and 120 c.c. Hare also proved that quantities of less than 40 c.c. did not kill dogs, and expressed his belief that an amount of air sufficient to cause death in a human being could not possibly enter a vein injured by a surgeon during an operation. Laborde and Muron have further shown that enormous quantities, 2,000 or 3,000 c.c., if introduced slowly and at intervals into the circulation of dogs, do not cause death. While not denying that death really may at times result from the sudden entrance of air into injured veins, Welch and Nuttall ("A Gas-producing Bacillus—*Bacillus aerogenes capsulatus, nov. spec.* Capable of Rapid Development in the Blood-vessels after Death," *Johns Hopkins Hospital Bulletin*), have reported some important investigations that will serve to clear up many, if not all, of these mysterious cases. In the case of a man who died rather suddenly after repeated copious hemorrhages from a large sacculated aneurism of the aorta, which had ruptured through the anterior thoracic walls in two places, the heart and blood-vessels, eight hours after death, were everywhere found to contain gas-bubbles in large amounts. The gas was inflammable, and was, therefore, certainly not atmospheric air. Smear cover-glass preparations of the blood showed myriads of capsulated bacilli wherever this gas was found. The micro-organism was isolated in pure culture and found to be an obligatory anaërobe. The bacillus, which varies in size, averaging from 3 to 7 μ in length, is non-motile, does not form spores, is, as a rule, surrounded by a distinct capsule, grows on all ordinary culture-media under anaërobic conditions, and stains well with the usual aniline dyes. Pure cultures in sugar-bouillon, injected into the circulation of rabbits just before death, reproduced in every particular the conditions found in the body of the patient, so far as the presence of gas and the changes caused by the bacillus are concerned. Welch and Nuttall express the belief that the bacilli entered the aneurismal sac through the external openings in the chest-wall before death, and, though speaking with reserve on this point, they think that the gas produced may have had something to do with the death of the patient. We do not know whether cultures have before been made in such cases, but even if they had been made by the ordinary roll and plate methods, it would not be surprising that no results were obtained, since, as has now been discovered, the bacillus is anaërobic. This instance shows the advisability of adding, as a matter of routine, to our ordinary culture-methods at autopsies, a few tubes to be grown in the absence of oxygen, a matter of little difficulty since the introduction of Büchner's jars.

Vulvo-vaginitis in Children.—From a painstaking study of this subject published in the *Journal of Cutaneous and Genito-urinary Diseases*, November, 1892, Dr. E. Martin, concludes that: 1. Vulvo-vaginitis in children may be gonorrhœal or irritative. 2. Both forms are prone to occur among dirty, ill-nourished children. Scrofula and the exanthemata particularly predispose to the development of either form. 3. The gonorrhœal form is rarely acquired from criminal practices; it is usually carried from an infected mother to her child, either during birth or afterward, by means of the fingers, garments, wash-rags, or bathing water. It is characterized by inflammatory involvement of the urethra, vagina, and endometrium; is attended with fever, local pain, and often severe bellyache, and has a tendency to become chronic. 4. Gonorrhœal vulvo-vaginitis may occur at any age. It is probably more common in the first two years after birth. It may be complicated by gonorrhœal ophthalmia; by gonorrhœal rheumatism; by any of the complications and sequelæ of gonorrhœa in the adult. Its discharges are highly contagious, not only by actual contact, but through the medium of bath, bedclothes, and garments. Hence a prompt diagnosis is of extreme importance, and in institutions cases must be separated from other non-infected inmates. 5. A positive diagnosis can be made only after microscopic examination of the urethral discharges. Since the disease may be acquired in many ways impossible to trace, and since competent observers state that there are other micro-organisms in the vulvar discharges of vulvitis identical in appearance and staining reaction with gonococci, great weight cannot be attached to the finding of these bacteria in medico-legal cases. 6. The treatment consists in frequent injection of the vagina by means of an irrigator and a small soft rubber catheter, with hot soda solution, followed by hot bichloride solution 1 to 10,000, or silver solution 1 to 6,000; dusting of the vulva with finely powdered zinc oxide powder, and dressing with dry cotton inserted between the labia. Cure usually results in three to five weeks. Sometimes, when parents are careless of treatments, the inflammation becomes chronic and runs on indefinitely. 7. The catarrhal or irritative form of vulvo-vaginitis is most frequent from the fourth to the sixth year of life. It may be excited by attempts at rape or other traumatism. Its commonest cause is seat-worms and dirt. 8. It is not yet proven that this form is contagious, or is followed by any of the complications of the gonorrhœal form. It rarely invades the urethra, often spares the vagina, and occasions but slight local symptoms and no systemic disturbance. Exceptionally it may be the precursor of local diphtheria or gangrene (noma pudendi). 9. Except in the scrofulous, cachectic, and persistently dirty, it quickly yields to mild cleansing and astringent washes, and general tonic treatment.

Rhus Radicans in Enuresis of Childhood.—Dr. St. Philippe claims that in rhus radicans we have a remedy in nocturnal enuresis of childhood more certain and effectual than any hitherto recommended. He uses it in the form of a tincture—dried leaves, 1 part; alcohol of sixty-nine per cent., 5 parts—of which he prescribes, at first, five drops morning and evening to children of from two to six years. In rebellious cases, and in children over six years, he gives as high as twenty drops morning and evening. It is given in a little syrup and water.—*National Druggist.*

Too Much Needle.—A man recently brought suit against the proprietor of a London restaurant to recover damages for injury received in swallowing a needle with the spinach. He lost his case because he had no witnesses to prove that the needle was in the food.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, December 17, 1892.

THE ESTABLISHMENT OF A NATIONAL QUARANTINE.

THE experiences during the past months in connection with the threatened invasion of this country with cholera, and the grave probability that the disease will visit our shores with the coming of summer, have drawn attention to the necessities of the establishment of a more efficient quarantine system.

To such as have studied the question impartially, from the standpoint of general good rather than that of political expediency, there is but one verdict, and that is in favor of a national quarantine. By the praiseworthy efforts of the health officer of this port the disease was prevented from gaining a foothold in New York during the past season, and while it must be admitted, even by those who on general principles are opposed to the present system, that he did his duty and deserves all praise, the precedent is hardly a guarantee against future possible failures under existing regulations. It is not required of New York to take upon itself the principal burdens of responsibility and expense for protecting the rest of the country. It is notorious that the quarantine regulations in other ports of entry are relatively, if not positively, inefficient, and that a uniform system is urgently demanded. Senator Chandler's bill, advocating the suspension of immigration for a year, is a very reasonable measure under the circumstances, in so far as it may give time and opportunity for the perfection of a comprehensive and practical scheme for utilizing a new national law. It is a valuable auxiliary measure, but not such an absolutely necessary one as without it a good quarantine should be a failure.

The bill introduced by Mr. Payne, Member of Congress from Maryland, a summary of which was presented in our previous issue, has many excellent features, but appears too complicated to work well in practice. His advocacy of a National Bureau of Health is eminently proper, but the details of its working are not such as would commend themselves to the good judgment of practical sanitarians. The sentiment of the medical profession of this country, as we interpret it, is in favor of more centralization of power than is given by the bill in question. Generally the more commissioners there are for the carrying out of the provisions of any law the worse for the law. The National Health Board law would have been as near perfection as possible were it not that it aimed to do too much through its multiple commission. It is obviously proper to centralize rather than divide the responsibility of enforcement of any law for National Quarantine. The simplest way is by the formation of a National Health Department, making the Secretary of the same a Cabinet officer, who is to be appointed by the President, as are also the various chiefs of bureaus. At present, however, there are, as shown in opposition to the bill of Mr. Raynor, so many conflicting elements nursed by the respective friends of the defunct National Board of Health, on the one hand, and the Marine Hospital Service on the other, that the practical solution of the question is likely to be postponed until late in the Session. In the meanwhile we shall be ready to give still further discussion of the subject.

PROSTITUTION AND THE PUBLIC.

THE subject of prostitution has been forced into public attention of late. As is well known, an eminent clergyman of this city—deservedly esteemed for the sincerity and uprightness of his character, as well as for his eloquence and determined purpose—has been trying to prove three things: 1, That the New York police department receives fees or bribes from the brothels, saloons, and gambling houses of the city; 2, that they know of the existence of these places, yet do not close them up, or restrict their activity, as the law directs; and, 3, that they ought to be closed, or restricted more thoroughly. The police department naturally deny the bribe-taking, and they appear to assume the position that brothels and gambling-houses must exist, and cannot safely be entirely suppressed. There is a very wide-spread conviction that the brothels and gambling-places do pay tribute, though it is hard to prove; Dr. Parkhurst, however, probably has the sympathies of the public with him in his first indictment.

With regard to the proposal for the entire and immediate suppression of houses of ill-repute, as advocated, the idea is impossible, Quixotic, and dangerous. A study of the subject from a scientific and sociological point of view would convince one of this, even if common sense did not show it. There are, perhaps, over two thousand houses of ill repute, and twelve or fifteen thousand professional prostitutes in this city. Statistics on the point can only be approximate. These prostitutes represent a special, degenerate, and, in a sense, criminal class. According to Jarnousky, nearly one-half present pronounced stigmata of degeneration; they are more decidedly a class by themselves, an anthropological species, than professional thieves. Over ten per cent. are of illegitimate parentage, a considerable proportion are born of alcoholic, syphilitic, adulterous, or criminal parentage. A large proportion have morbid sexual propensities and crave sexual excesses.

A very typical and instructive history of a prostitute is that of *Alphonsine Plessis*, a character immortalized and idealized by Alexandre Dumas in his novel and play, "La Dame aux Camellias." Her paternal grandmother, who was half-prostitute, half-beggar, gave birth to a son by a country priest. This son was a kind of country Don Juan, a pedler by trade. The maternal grandmother was a nymphomaniac, whose son married a woman of loose morals, by whom a daughter was born. This daughter

married the pedler, and their child was the Lady of the Camellias. Said lady had unquestionably the powerful and perverted sexual instincts of many of her class. She died childless, early in life, from consumption, Nature thus extinguishing the race.

People with the ancestry, the habits, the perverse instincts, of the prostitute class cannot be cured or reformed by the enforcement of municipal ordinances. If taken from their surroundings and placed where they can earn an honest livelihood, they, as a rule, go back voluntarily to their old mode of life. And they do this despite the fact that this life is always a short one, and is sure to end in sickness, degradation, and misery.

It would be absurd to suppose that adultery would be lessened or that prostitutes would cease their work if driven from their houses. A thief is just as much a thief whether in a hotel, a boarding-house, or in his own headquarters. All that municipal authorities can do as yet is to reduce the number as much as possible, make prostitution difficult, and prevent the disorderliness and the grossly lascivious performances which it has been shown are carried on in some places. This is not beyond the power of an efficient police.

As to the plan of licensing the brothels, Superintendent Byrnes would not have recommended this if he had made himself more familiar with the working of such methods elsewhere. It has been found that licensing has a tendency progressively to lessen the number of public houses; the women refuse to be registered, inspected, and have their liberty restricted. They go off to other places. This has been the experience in Paris; and such is the conclusion recently reached by Dr. O. Lassar (*Annals de Hygiène Publique*, November, 1892), who has been investigating the subject. In fact, by a curious *contretemps*, Superintendent Byrnes has proposed a remedy which would do eventually exactly what he blames Dr. Parkhurst for attempting now, viz., it would drive the prostitutes out among tenement, apartment, and boarding houses.

BRADYCARDIA AND THE ACTION OF ATROPIA ON THE HEART.

That peculiar condition of the heart in which a decided slowing of normal cardiac action is the only symptom is known as bradycardia. It is not an easy matter to trace this symptom to intra- or extra-cardiac disturbances. Dr. Dehio claims that by the aid of atropia this question can be decided. In the *Centralblatt für klinische Medicin*, No. 42, 1892, his studies on this subject are referred to. It is known that atropine paralyzes the intra-cardiac fibres of the pneumogastric nerve. Bradycardia which is due to excitation of the bulbar centre of the vagus nerve, or of its cardiac branches, may be controlled or inhibited by the use of atropine. A case of apoplexy is cited, in which the cardiac beats rose from forty-eight to one hundred and forty-four after a hypodermic injection of atropine. But in three other cases in which the bradycardia was the result of changes in the heart itself, atropine produced no effect. Dr. Dehio also believes that bradycardia is most frequently caused by changes in nutrition of the cardiac nerve apparatus. Local sclerosis of the branches of the coronary arteries is, according to him, a common pathological condition, associated with this symptom. Finally, he argues that some cases are due not to organic changes, but to temporary functional disturbances. Altogether it is apparent that further studies are needed before the subject of bradycardia can be removed from the field of speculative reasoning.

THE DOCTOR'S INTEREST IN GOOD ROADS.

The question of cycling is one that has attracted considerable attention of late from medical men, and while much has been written in favor of the practice not a few have raised their voices against it as being in many ways injurious, especially to growing youths. It is in moderation unquestionably of benefit to the full-grown man whose days are passed in the counting-room and whose hours of recreation would otherwise also be passed indoors, but like everything else it is liable to be carried to excess when it becomes a source of danger to health.

However we do not propose at this time to discuss cycling as a form of exercise, but would briefly refer to a reform of special interest to the country practitioner which wheelmen are working to bring about, namely, the betterment of our public roads. It is a deplorable fact, due no doubt in great measure to the conditions of our country's growth, that we have the worst highways of any nation of the civilized world. In the early days of the republic our roads were not so bad, although even then capable of improvement, but since the advent of the railway the highway has suffered from studied neglect. And in the Far West the railroad preceded settlement, so that the wagon-road was of very secondary importance in the eyes of the short-sighted pioneer.

But with the use of bicycling the wretched condition of our highways has become a subject of more general comment, and the wheelmen have set themselves to work to arouse the community to a full appreciation of the loss of time, money, and enjoyment occasioned thereby. It has been proposed to have a special department of road-making at the Chicago Fair. The advisability of having road-making a subject of special instruction in our colleges has been suggested, and Mr. Albert A. Pope, of Boston, has also circulated a petition calling upon Congress to create a Department of Roads as one of the branches of the general government at Washington.

Of course, the wheelmen are led to agitate this subject for their own benefit, as nothing is more disheartening to a cyclist than a long stretch of bad road, but the matter concerns more nearly the farmers and especially physicians practising in rural districts. The farmer may often choose his time for going out, and he may perhaps be able to wait until the roads are, comparatively speaking, passable before taking his grain to market, but the doctor cannot wait. No matter what the condition of the road he must go out when he is called and ride perhaps miles over dirt roads beside which the maligned "corduroy" is as a billiard-table. A smooth, well-kept road would save him many an hour and many a dollar which he now spends for repairs to his buggy. This movement is therefore one that concerns him most closely, and he might well exert his influence in the community in seconding the efforts of the cyclists to secure roads which shall be a help rather than a hindrance to communication.

RAILROAD SURGERY.

Much attention is being called to the fact that "Railway Surgery" is to have a separate section at the Pan-American Medical Congress. Why there should be such a specialization as this it is a little hard to understand. Railway surgery must surely be conducted on the same principles as ordinary surgery; a fracture, a sprain, a lacerated wound, cannot have any specific qualities because they were produced during a railway collision. It seems unlikely that a railway surgeon should need or should possess a special kind of technique or therapeusis.

As a matter of fact, we believe that the attempts at making the railway doctor a separate brand of the genus surgeon are a mistake. There is a justification for this sort of work, however, which is based on a kind of medical economics and the doctrine of expediency. The railway surgeon in this country represents a peculiar social feature of our institutions. He is not an independent professional man, but is the employee of a corporation and the servant of the same. The organization of these employees is probably a benefit to them, in that they secure unity of action in their attitude to the corporations. Associations of railway surgeons have, therefore, their special function in studying the business part of their profession, not the scientific.

AURICULAR VERTIGO AND DROWNING.

A French physician has recently come forward to dispute the popular notion that deaths by drowning are due to "cramps." In the *Northwestern Lancet*, these observations are made the subject of editorial comment. Our esteemed contemporary says that "A little reflection will show that to suppose these sudden deaths by drowning to be caused by cramp is to adopt an explanation that has several weak points. There is nothing about a cramp in the calf to make a good swimmer sink. Even if the pain be so severe as to induce him to keep his legs still, it is no difficult task for the expert bather to swim with his arms alone, to say nothing of floating on his back, an accomplishment which few swimmers fail to learn. All boys who have been in the water much know that one of the feats easily learned is to swim with "no legs" or "no arms," and it is certain that nothing less than a weight attached to the legs would pull a good swimmer under if he had free use of his arms. The man with cramp would at least be as well off as he who, unable to swim at all, falls overboard; such an one usually sinks and comes up two or three times before going under forever, struggles violently, and usually succeeds in crying out for help. It is noticeable on the other hand that the supposed victims of cramp usually sink at once, often without a cry, and rarely come to the surface again."

The views of Dr. Rutten, the French author referred to are, thus explained. Aural vertigo is the true cause of many accidents by sudden drowning. Dr. Rutten gives instances of swimmers who have been attacked with giddiness while in the water, in whom the subsequent symptoms of deafness and ringing in the ears has led to the discovery that the cause of the trouble was the pressure of water in the auditory canal, particularly where a wave has struck against the side of the head, a blow that has been known even to cause a rupture of the membrana tympani. Particularly is there danger of vertigo from the pressure of water in the ear if there be a perforation of the membrana tympani, no matter how small, for then the pressure may be brought directly to bear upon the fenestra ovalis and so affect the internal ear, whose semicircular canals are supposed to be the organs that preside over the equilibrium. In some cases no doubt the pressure may be increased by the presence in the external auditory canal of a plug of wax or a forgotten wad of cotton, which becoming dislodged or swollen may act as a piston in a syringe in increasing the pressure of the air upon the middle ear.

Among the cases described by the author, one is peculiarly instructive. It was the instance of a man who would certainly have drowned but for timely assistance, as he at once lost all control over himself. In another case the swimmer disappeared suddenly under water, but was rescued at once by divers. When he came to he said that he felt water enter his ear and immediately became dizzy and lost consciousness. Examination of this man's ears showed a slight and entirely unsuspected perforation of one of the drum-membranes.

The Lancet concludes by the following judicious observations: "The explanation thus furnished of some of the deaths by drowning is far more satisfactory than the old one of cramp, since the vertigo and unconsciousness are sufficient to account for the suddenness with which many swimmers disappear under water and the absence of the struggle for life that is to be expected under the circumstances. The practical moral it teaches is that those who have perforations of the drum-membrane should be particularly cautious about getting water into the ear while swimming, and should, as a safeguard, wear a suitable wad of cotton in the meatus."

Lawyer's Fees as Contrasted with Those of Physicians.—Thirty thousand dollars is not a very unusual fee for legal service in the defence of wealthy criminals, or in cases involving large interests. The slayer of Jim Fisk paid to his lawyer about two hundred thousand dollars. The late Hall McAllister received a fee of twenty thousand dollars on a compromise case and did not even appear in court. To the personal knowledge of the writer his time and labor in this case did not equal that of a surgeon who amputates a leg. The late John B. Felton received from James Lick fifty thousand dollars for setting aside his first deed of trust. A young and inexperienced attorney demanded a five thousand dollar fee in a breach of promise suit, the trial lasting a week. Attorneys by the dozen in San Francisco have received fees ranging from five to fifty thousand dollars. In the settlement of large estates attorneys' fees not infre quently reach one hundred thousand dollars. The attorney's fee in the Charles Lux estate will exceed a quarter of a million.

What's in a Name?—The inhabitants of Tottenham, London, have been greatly distressed because it was proposed to erect a new fever hospital there, and they feared the region would get a bad name. They have been pacified, however, by the promise of the authorities to call the institution the North-Eastern Hospital instead of the Tottenham.

News of the Week.

Honors to Medical Inspector Rufus J. Tryon, U. S. Navy.—General Crespo, Provisional Governor of Venezuela, has forwarded to Dr. Tryon, Fleet-Surgeon of the U. S. Squadron recently serving in Venezuelan waters, a letter of personal thanks for meritorious services, and the decoration of the Bust of Boliviæ. This South American order has been hitherto bestowed on two other distinguished North American surgeons, Drs. Samuel Sexton and Robert F. Weir, of New York.

The First Annual Dinner of the Alumni Association of the New York Hospital was held at the Hotel Marlborough on the evening of December 10th. Professor Thomas M. Markoe presided and acted as toast-master. The following toasts were responded to as follows: "Our Governors," Mr. E. T. Gerry and Mr. W. W. Hoppin; "Our Executive," Mr. George P. Ludlam; "Our Sister Societies," Dr. D. Bryson Delavan and Dr. W. R. Townsend; "The Old Hospital," Dr. D. B. St. J. Roosa and Dr. George F. Shrady; "The New Hospital," Dr. Walter Vought; "Our Emigrants," Dr. W. Wainwright, of Hartford, Conn.; "The Undergraduates," Dr. John Rogers. This association, composed of the graduates of the New York Hospital, was organized March 23, 1892, with Dr. Thomas M. Markoe, the oldest graduate (1842), as president, and has held three meetings since that time. The original officers were re-elected for the ensuing year, as follows: *President*, T. M. Markoe; *Vice-President*, W. Gilman Thompson; *Secretary*, E. T. Doubleday; *Treasurer*, H. A. Griffin; *Executive Committee*, F. P. Foster, Chairman, G. Roe Lockwood, C. M. Garrison; *Committee on Admissions*, C. S. Cole, Chairman, W. F. Martin, George H. Cobb; *Committee on Entertainment*, J. Adams, Chairman, Paul T. Kimball, P. C. Bolton.

Professional Services or Contempt.—A correspondent sends us the following card, clipped from a Cherokee County (N. C.) paper: "Dr. ——, physician and surgeon, tenders his professional services to those who are willing and do pay, and to those who are willing but cannot pay, but offers his contempt to those who are able but will not pay."

The Physicians in Monte Carlo are said to be forbidden access to the gambling-rooms in that principality. This is not because of any special concern on the part of the croupiers for the doctors' morals, but because they are trying to get their living in an honest way, like the waiters, undertakers, and tradesmen. They and their families are, however, graciously allowed free access to the concert-room.

The Right to Cross the Line of a Parade.—The aldermen of this great town appreciate the medical profession. They have given the right of way to physicians' carriages, and have recently passed an ordinance allowing physicians to cross the line of a parade or a procession.

The Association of Southern Medical Colleges was organized at Louisville November 17th. It includes fifteen Southern colleges. The permanent officers elected are: *President*, Dr. J. M. Bodine, of Louisville; *Vice-President*, Dr. W. D. Haggard, of Nashville, Tenn.; *Secretary and Treasurer*, Dr. G. C. Savage, of Nashville. Unless otherwise ordered by the President, the annual meetings of the Association will be held at the same times and places as the Southern Surgical and Gynecological Association. The new regulations with regard to the college courses, etc., will go into effect with the sessions for 1893–94. These regulations require attendance on three full courses of lectures of six months each; also a certain standard of education before matriculation.

The "Archivos de la Policlinica" is the name of a new medical journal published in Havana. The first two issues present a very neat appearance, and contain, besides clinical reports, a number of reviews of recent publications, and the usual abstracts of medical progress.

Preventive Inoculation for Cholera.—M. Hafikine, of the Pasteur Institute, is about to proceed to India to endeavor to apply his method to practical use in the saving of life in the regions of endemic cholera in British India and possibly in Siam.

Dr. G. E. de Schweinitz has recently been elected Clinical Professor of Ophthalmology in the Jefferson Medical College of Philadelphia.

A Royal Heart for Sale.—The heart of the French Dauphin, son of Louis XVI. and Marie Antoinette, was removed at the autopsy ninety-seven years ago, and has been preserved in alcohol ever since. The heart was in the possession of Dr. Pelletan who performed the autopsy. His son having recently died, the specimen is to be sold at auction.

First Annual Mexican Medical Congress.—A telegram from Mexico states that the first annual congress of the Mexican Medical Association closed its four days' session at Mexico City, December 12th. A number of interesting papers were read by prominent physicians of the republic. One of these that has attracted much attention was that of Dr. Carmona Y. Valle, on the subject of "Yellow Fever," in which the eminent authority related his investigation of that disease and the results obtained by his treatment of many cases by inoculation. He claimed that the inoculation method was highly successful where properly conducted, and that it was no longer a theory, but a practical preventive remedy. The paper contained many new propositions concerning yellow fever that have caused a considerable stir among the medical fraternity of Mexico.

The Deaths from Surgical Operation in this City during 1891 were 133 (*New York Medical Journal*). Ten per cent. of these deaths were due to the operations of circumcision, done presumably in those cases by rabbis. The greatest single item was that of deaths from laparotomy; these numbered seventy-six, or fifty-seven per cent.

Tobacco and Cholera.—The Berlin correspondent of the *British Medical Journal*, referring to the large trade in cigars manufactured in Hamburg, states that experiments made in the hygienic institute of the Berlin University have shown that the cholera bacilli die more quickly on dry tobacco than on dry glass-plates; that they do not multiply but quickly die on moist tobacco, and that tobacco-smoke quickly kills the bacilli.—*New York Medical Journal.*

A Medical Centenarian.—The death of Dr. Enoch Fithian, of Bridgeton, N. J., on November 15th, removes the oldest living medical graduate, as he was reported to be, of the University of Pennsylvania, from which institution he received his diploma in medicine in 1815. He was born in May, 1792.

The Chamber of Commerce of New York and National Quarantine.—The Chamber of Commerce held a special meeting December 13th, to receive the report of the Special Committee on Quarantine appointed on September 9th, which consists of Alexander E. Orr, Seth Low, Samuel D. Babcock, J. Pierpont Morgan, and Austin Corbin. Mr. Orr, who is vice-president of the Chamber, presided, in the absence of President Charles Stewart Smith, and Mr. Low read a voluminous report, with the appended reports of the Advisory Committee of Physicians.

The reports condemned the present system of quarantine in New York, and advised in favor of Federal control, giving reasons substantially as follows :

"1. The Federal Government being an indispensable factor in every quarantine crisis, it is only by giving to the Federal Government complete control that conflicts of authority and the weakening effects of official jealousy can be avoided.

"2. The Federal Government, in every crisis, through the various arms of the public service, is able to command an amount of expert co-operation entirely beyond the reach of a State Department.

"3. The Federal Government has at command the trained men who have to be summoned to the help of the State in time of peril. It is better to have the Federal Government directly responsible, instead of indirectly.

"4. To these may be added the further consideration that the co-operation of consuls with the Quarantine officials is a matter of growing importance. The Health Officer complains that he failed to receive the aid from this quarter to which he was entitled. It is clear that these officers would be less likely to be at fault as toward federal officials."

"5. An international supervision of infectious diseases is a probable and a very desirable outcome of recent experiences. Such an outcome of itself would necessitate a national Quarantine."

The committee concluded the report by offering the following resolutions :—

"*Resolved*, That the Chamber of Commerce memorialize the President and the Congress of the United States to enact, as speedily as may be, a suitable law placing the control of Quarantine at New York and at all other places under national control.

"*Resolved*, That the attention of Congress is respectfully directed to the injurious influences that continued indiscriminate immigration may have upon the welfare of this country, in the hope that careful investigation relative thereto may be promptly had.

"*Resolved*, That the thanks of this Chamber be extended to the Advisory Committee of Physicians for their invaluable services in connection with the recent quarantine at New York.

"*Resolved*, That the President of the Chamber of Commerce be requested to convey to the Governor of the State, His Excellency Roswell P. Flower, and to the Secretary of the Treasury of the United States, the Hon. Charles Foster, the high sense of appreciation in which this Chamber holds their active, intelligent, and public-spirited services during the recent quarantine."

The Late Dr. James R. Leaming.—At a meeting of the Faculty of the New York Polyclinic, held December 9, 1892, the following preamble and resolutions were adopted :

Whereas, It has pleased Almighty God to remove our beloved President and Emeritus Professor of Diseases of the Chest and General Medicine, Dr. James R. Leaming ; therefore be it

Resolved, That in the death of Dr. Leaming we recognize the loss to ourselves of a faithful officer and a trusty counsellor, and to the community at large of a skilful physician of great attainment, and a loyal and eminent citizen ; a man of rare geniality and cultivation, a stanch friend and a Christian gentleman, whose extraordinary gentleness, tender sympathy, and, above all, exemplary life, had crowned his advancing age with honor, surrounded him with devoted friends, and made his career well worthy of study and of imitation. His memory will be universally cherished and his name placed among the number of those who are illustrious.

Resolved, That the deep sympathy of this Faculty be extended to the family of the deceased, and that the foregoing be incorporated in the minutes of this meeting, published in the leading journals, and a copy sent to the family.

D. Bryson Delavan, M.D.,
R. C. M. Page, M.D.,
W. H. Katzenbach,
Committee.

The Late Dr. Robert Warren Greene.—*Whereas*, In the death of Dr. Robert Warren Greene, the Society of the Alumni of Bellevue Hospital has lost a fellow-member who, by his geniality and kindness of heart, endeared himself to all ; and,

Whereas, The members of this Society desire to show their sympathy and grief at the death of a man who gave such brilliant promise of an eminent and successful professional career, and whose nobleness of character, fine sense of honor, and many acts of charity and kindness to all who were in sickness and trouble, were appreciated by those who knew him more intimately.

Resolved, That we express, in so far as words may, the realization of the great loss sustained not only by this Society, but by profession and community, and extend to his bereaved family our heartfelt sympathy in their affliction.

And as a fitting tribute to his memory, be it further,

Resolved, That these resolutions be spread upon the minutes of this Society, and that a copy be sent to his family and to the medical journals of this city.

Egbert Le Fevre,
Austin Flint, Jr.,
William Evelyn Porter,
Committee.

Dr. Allchin lectured on duodenal indigestion recently before the Royal College of Physicians.

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, November 21, 1892.

SAMUEL B. W. MCLEOD, M.D., PRESIDENT, IN THE CHAIR.

Diet and Digestion: Their Influence on the Voice.—DR. J. MOUNT BLEYER, read a paper on this subject and demonstrated the alcoholic voice on the phonograph. The introductory part of the paper was written philosophically regarding digestion and diet. The next part of it was taken up with physiological discourse—as that of alimentation; the dual construction of man, and healthy alimentation; the wear and tear of the body and its reconstruction; the composition of foods; the composition of man and his nutrition. Then the precautions in alimentation to be observed with a view of preserving the integrity of the voice, dos and don'ts. He divides alimentation under two heads—the healthy and the unhealthy. In the healthy alimentation he meant the feeding upon diet or those kinds of foods which any animal or organism is designed to live upon, as indicated by the structure and functions of its digestive machine. The unhealthy is the feeding, again, upon food which the digestive organs cannot readily and perfectly digest, many comparisons being resorted to showing the truth of the reasoning. He gives a healthy bill of fare, and, as the night meal is of importance, he specially directs the patient to eat such food as will quickly digest, and such kind as will not produce either flatulence or fermentation. Many catarrhal troubles of the nose, throat, ear, and chest may be laid at the door of improper food, and therefore the digestive organs can be taken into account ninety times out of a hundred. He speaks of having had good results in those catarrhal diseases, by a simple, rigid regimen and local treatment. This method of healthy feeding, when once begun, must be kept up for the entire life. Deviation therefrom one must always pay for, according to the ratio of his deviation. Under the heading, the Composition of Man and His Nutrition, he speaks of vegetarianism at length in pros and cons, and then gives his modification of a vegetarian diet, to be adopted in individual cases. His modification consists in utilizing fats as an economizer of the albuminoids, and says that a vegetarian dietary, in which animal and vegetable fats enter freely, is a very much fuller and likely to be very much more satisfactory one than that from which all animal fats, except butter and cream, are excluded. This dietetic regimen he uses in complicated nose and throat diseases, with gout, rheumatism, or in any dyspeptic disorders that come under his care. He specially maintains that all cases must be individualized.

Choice should be made of those articles of diet which do not tax excessively the powers of the stomach. The special feeding indicated by the condition of the system acts as a means of cure in all diseases arising from unhealthy feeding. He says that healthfully feeding those tissues which require nourishing, and starving such as have been overfed or unhealthily fed, will in time restore the equipoise of an unbalanced organism. In order to exhaust the subject he was obliged to place most rules under heads of dos and don'ts. Among them he takes up the question of water-drinking—hot and cold—alcohol, beverages of all kinds, with the whys and wherefores. Then he touches upon the home usage of the Carlsbad waters and salts, both physiologically and therapeutically, indications, and contra-indications. Concluding with the question of smoking in its bearing on the care of the voice, with many other interesting points of value to voice-users.

After the reading of the paper he demonstrated by means of the phonograph a specimen of alcoholic chronic laryngitis as found in drinkers, contrasting this with a non-alcoholic voice. The phonogram was most true—as a record.

DR. J. R. MACGREGOR said, with regard to the difference between nitrogenous food and the carbo-hydrates, that late physiological investigations had shown the latter to be as much a source of muscular power as the former. The ox, for instance, put forth as great strength as any of the carnivora. The difference seemed to be not with regard to the amount of muscular force produced by the two kinds of food, but in the manner of its expenditure. The carbo-hydrates, including the vegetables, might be said to be the foundation of force, while the nitrogenous foods were for the discharge of energy.

He endorsed most of the propositions with regard to the use of food contained in the paper. It was not the eating alone, however, that tended in civilization to make life short; regulate our diet as we would, we still would not attain to the age of the South American physician, one hundred and ninety years, if we continued to live in other respects as we do in our cities. The emotional side of life had as much to do with the exhaustion of energy as the intellectual.

It would have been interesting, had the length of the paper permitted of more detailed reference to the influence of particular foods upon the different organs concerned in the production of voice, and the manner in which the changes in the local tissues modified the voice. Some writer had suggested that the injurious influence of alcohol in the throat was centred especially upon the epiglottis, but the speaker thought it would be found more general. Then there was the nervous influence produced through the recurrent laryngeal. He heartily endorsed all that had been said with regard to vicious results of alcohol.

DR. F. J. QUINLAN made some remarks upon unhealthy feeding and the use of alcoholics in causing congestion, this in turn resulting in pressure in the vocal apparatus, and thus interfering with voice.

Dietary Rules.—DR. J. H. TYNDALE thought two statements were applicable to the general subject: 1, The general condition should claim attention prior to the local; 2, discretion in prescribing the diet. Dietary rules could be laid down as follows: 1, For no one meal should there be a multiplicity of dishes, seldom should more than four be allowed; 2, the food should be plain, nothing particularly acid, spicy, etc.; 3, every mouthful should be chewed from twenty to thirty times (the Gladstonian method was a good one); 4, long intervals between meals, giving ample time for digestion and rest of the stomach afterward. Exceptions to the latter rule applied in acute wasting disease and in fat people, who should take one article and at more frequent intervals. Proper diet always meant a compromise between things which the patient liked and the physician's judgment as to what was best for him.

Heart of a Suicide.—DR. THOMAS H. MANLEY presented the heart of a young man who had shot himself twice through the lower chest with a view to committing suicide. One bullet had passed through the pleura and grazed the left ventricle; the other entered near by. The hemorrhage was internal. The temperature remained normal about twenty-four hours, then it rose, pleurisy set in, and between the loss of blood and inflammatory affection, death was caused in three days.

Incomplete Hernia Operation.—Dr. Manley presented a portion of the sac in a case of strangulated hernia which he had been requested to operate upon, but being then unable to go, the family physician operated, with assistance, and supposed he had reduced the hernia. Next day the symptoms became worse, and Dr. Manley found a tumor still present which proved to be the strangulated gut, the former operation having resulted only in reduction of the sac. The patient recovered.

A New Instrument for Dilatation of the Cervix Having a Vagino-uterine Curve.—DR. JAMES STAFFORD exhibited and described a new bivalve instrument for dilating the cervix uteri. He showed the necessity for such an instrument having not only a curve corresponding to

that of the uterus, but also one conforming to the curve of the vagina. The intra-uterine portion had tapering blades, not of very large size, as it was intended for dilatation and not divulsion. A bulb separated it from the vaginal portion to obviate introduction too far. The instrument was especially useful in cases of imperfect uterine development, attended by flexion, dysmenorrhœa, and sterility.

Opposed to Uterine Dilators.—Dr. George T. Harrison said he was opposed to uterine dilators, especially in the hands of general practitioners. Harm had often resulted from them. If dilatation were really necessary, it should be done gradually, as one dilated the urethra, by the introduction of graded sounds. With due antiseptic precautions, the laminaria tent could be employed. Rapid dilatation by bivalve instruments without an anæsthetic caused pain; it was liable to injure the tissues; the pressure was at two points only, instead of uniform all round like in using sounds.

Dr. H. J. Boldt said when he used a bivalve dilator he preferred one which was corrugated so that it would not slip. Any form of rapid dilatation was dangerous if done in one's office. It should be made an operation, with corresponding precautions, and performed at the patient's house, or in a hospital. The laminaria tent was useful, but must also be surrounded by antiseptic precautions.

Dr. Truax saw a decided advantage in the curve of the instrument presented over other bivalve dilators without the curve.

The President coincided with this remark, but said he preferred the sponge or laminaria tent.

The Author would prefer dilatation to the tents. He did not mean divulsion. Everything was aseptic when he used the dilator, as it was preceded and followed by tampons and antiseptic applications.

MEDICAL AND CHIRURGICAL STATE FACULTY OF MARYLAND.

Semi-annual Meeting, held at Easton, Md., November 15 and 16, 1892.

Dr. L. McLane Tiffany, President, in the Chair.

The Address of Welcome was delivered by Dr. E. C. Trippe, in which he greeted all the physicians present and thanked them for making Easton their place of meeting.

The President's Address was then delivered by Dr. L. McLane Tiffany. He thanked the profession of Easton for their cordial welcome, and urged on everyone present the importance of joining this, the State Society. This was the first meeting since the passage of the new medical law restoring to it the old right of granting the privilege of practising medicine in Maryland, and for this reason all regular members of the profession in this State should now become members of this society, and thus have their say as to who should practise in this State.

He said that all good work was not done in the great laboratories of the cities; that two of the greatest investigators and benefactors had done their best work while practising in the country; the one was Jenner and the other was Koch. He showed an old book of the last century that had been written by a practising physician of Easton, and which had many things in it which would still hold good at the present day.

The Modern Treatment of club-foot was the subject of a paper by Dr W. B. Platt. This subject is always important and has always elicited attention. Cases should be treated early to be treated successfully, but there are not many good results without operation. The disease may be local or of central origin. When subcutaneous tenotomy began to be practised, the results of treatment were better. In replacing a foot violent twisting does good; it may sound harsh, but it does not do the harm one would think. In these cases the foot is usually somewhat deficient in development. After tenotomy came the plaster bandage.

Formerly the foot was let go for ten days after operation, because it was thought not well to put it up at once. The next step was overdistention by means of an apparatus. Some had advocated excising a wedge-shaped piece, but this was not good. When the foot was replaced the bones had to form new facets. The resistance is much greater in congenital than in acquired club-foot, unless it has been walked on for a long time.

Dr. Hiram Woods asked what was the prognosis in infantile paralysis, and in all paralytic cases.

Dr. Platt said it depended on the time it had gone on. If too old, not much good can be done. If the motive power either in the brain or in the nerves be destroyed, nothing can be done. Sometimes the muscles can be brought to do something by faradization.

The Amœba Coli; its Importance in Diagnosis and Prognosis.—This was the subject of a paper by Dr. W. T. Howard, Jr. Since the first case by Osler in this country, it has been found several times. Councilman and Lafleur had reported fifteen cases. The amœba coli is about ten to twenty micro millimetres long; it has an ectosarc and an endosarc, and has two kinds of motion, a sort of wriggling motion and that by the aid of pseudopodia. These pseudopodia were very active at the body temperature, but became quieter as the temperature rose. The amœba may contain vacuoles, blood-corpuscles, fat-corpuscles, etc.

There are three kinds of dysentery with this amœba, the moderate, the grave, and the chronic dysentery. Diarrhœa is the principal symptom of the disease. The worst complication is abscess of the liver, and it occurred in eight of the fifteen cases of Councilman and Lafleur. The amœba can be found very easily in the pus of the liver abscess, or in a part of the stools.

Dr. S. T. Earle said that he had seen one case, and thought it was easy to recognize the amœba by the microscope. He should like to ask about the intermittent character of the diarrhœa. In his case he gave quinine internally and quinine by irrigation, and the man improved rapidly.

Dr. L. McLane Tiffany, in speaking of the clinical aspects of the case which had first led to the discovery of the amœba in this country, said it was in a young Hebrew physician, who had lived in Central America for some time and had suffered from dysentery and Chagres fever. He got better and finally went to Europe. There he got better and worse, and had exacerbations of fever with a subnormal temperature every seven days. His pulse was rapid and liver enlarged. He had made the diagnosis of multiple suppurative hepatitis.

Dr. William A. Canfield asked the size of the amœba under the microscope, as compared with other objects whose size was better known, and asked if the movements could be actually seen; or was there only a difference in shape when observing at intervals as there was with other amœbæ. Dr. Osler had shown him these amœbæ under the microscope, and his recollection of them was that the movements were not markedly active.

Dr. W. T. Howard, Jr., said in conclusion that he had purposely avoided saying anything about the treatment. Quinine had been used by some, and others preferred morphine and the sulphate of magnesium. It was not blood infection; the amœbæ are too large to get into the circulation and pass through the smallest capillaries. The organisms pass from the intestines to the liver. Their movements are in some cases, under the microscope, very easily seen when the fluid is warm, but they are not clear when it is cool, and then it is necessary to make successive drawings to notice the difference.

The Nose.—This was the subject of remarks made by Dr. John N. Mackenzie. The nose is much more an organ of respiration than of olfaction. The air is warmed and rendered moist before reaching the lungs; we should

breathe through the nose and avoid mouth-breathing. He quoted many interesting and humorous references on the nose as an index of character.

Some of the More Common Forms of Nasal Stenosis.—Dr. S. K. Merrick read a paper on this subject. We have learned much about this in the last ten years. There are few straight septa There are deformed and thickened septa. Hypertrophic rhinitis is a common cause of stenosis; it is often due also to deviation of the septum. The most common forms of growths in the nose are the myxoma, fibromyxoma, and fibroma. He treated these growths with the thermo-cautery, cold snare, and chromic acid. The cautery was very satisfactory.

The Importance of Determining the Cause of Repeated Attacks of Earache which Subside Apparently without Injury to the Ear.—This was by Dr. Hiram Woods. Many of these causes are overlooked. Certain throat lesions, such as chronic follicular pharyngitis, may cause earache. Post nasal adenoid growths may cause deafness, even though they of themselves are not very severe.

Dr John N. Mackenzie said that the origin of congenital malformations of the septum was doubtful, and there were only theories as to this point. Morgagni's theory was that the septum grew faster than the bones of the upper jaw, and consequently became twisted on itself.

The Importance of Symptom-treating in Pulmonary Consumption.—This was a paper by Dr. William B. Canfield. He referred to our as yet unsuccessful attempts to find a specific for tuberculosis, and the difficulties of treating the gastro-intestinal, the febrile, the nervous, and other such important symptoms; and some of those symptoms were so prominent that they almost masked the real trouble. With our present knowledge our treatment of pulmonary consumption should be largely preventive, but when it has appeared, then the symptoms furnish the therapeutic indications.

Genital Tuberculosis in Women; its Frequency and Clinical History.—This was a paper by Dr. John Whitridge Williams. It is a subject that has only been noticed within a few years. Cohnheim and Babes have described it. At the Johns Hopkins Hospital, his duty was to examine thoroughly and record accurately all specimens from the gynecological department, whether they looked diseased or not. Out of 169 cases in which the tubes and ovaries were removed, in 2 cases tuberculosis was macroscopically evident—that is, one and one-fourth per cent.—and in 6 others of these cases a microscopical examination showed evidences of tuberculosis which would have escaped detection but for the careful and routine examination carried on there. This, then, made 8 out of 169 cases tuberculous, or four and three-fourths per cent. In 96 cases there was inflammation, and in 8 of these, eight and three-fourths per cent., it was tuberculous, or one tuberculous in every ten to twelve cases of laparotomy for disease of the ovaries or tubes, or suspected disease. There were 2 cases found on macroscopic examination, and 6 with the microscope, that is, seventy-five per cent. of these cases were unsuspected. From these figures we may say that genital tuberculosis is three times more frequent than is generally supposed.

The order of frequency of genital tuberculosis, according to his experience, in the organs is as follows: Tubes, uterus, ovaries, vagina, cervix, and vulva. Genito-urinary tuberculosis is three times less frequent in the female than in the male. This may in part be accounted for by the difference in the organs, the manner of life, etc., of the two sexes.

The three modes of genital infection in women are: 1. From the patient herself. *a*. Through the blood. This is frequent. *b*. From the peritoneum. *c*. From other organs, such as the lymphatic glands, inflammations, fistulous tracts. 2. From without, in numberless cases, as from the fingers, infected linen, coitus with men who are infected with genito urinary tuberculosis. A few bacilli may get into the vagina and uterus with the semen and be washed away, but in the tubes they are better treated. It is not absolutely certain that this can occur, but it is very possible. 3. From bacilli from the patient. It may occur at any age, but preferably between twenty and forty, during sexual activity; secondary tuberculosis is more common after forty. Inflammations of the vulva from tuberculosis are not very different from other kinds of inflammation, but they are characterized by their persistency. Tuberculous metritis is much like other cases of metritis.

The diagnosis can only be made accurately and correctly with the microscope. Cancer of the cervix is clinically like it. The prognosis is always grave, and secondary affections are to be looked for. The treatment is largely prophylactic.

Circumscribed Abdominal Dropsy Simulating Ovarian Tumor.—This was the subject of a paper by Dr. Robert T. Wilson. He was certain at first that he had to deal with an ovarian tumor. There was dulness over the ovary, but it was clear on each side on percussion. Change of the patient's position did not change the position of the fluid. He operated and withdrew about two gallons of a pale yellow-greenish fluid, and in the bottom of the sac he found an agglutinated mass of intestines firmly adherent to the bottom of the sac. The mass measured 9½ x 6 x 3 inches, and was very much like a tumor. The walls of the sac were covered with small gray tubercles and were festooned with lymph. He removed the ovaries and tubes, and on microscopic examination they were found to be tuberculous. The patient had never been sick a day before she was pregnant. It was natural to suppose that she had a tumor, and had he tapped her as he had at first intended, he would not have been the wiser. Sir Spencer Wells has reported a similar case. He thinks an exploratory incision is very important More lives are lost through want of it than because of it.

Dr. T. A. Ashby said that the subject of genital infection with tuberculosis was very important, but that he himself had had no personal experience with it. We have gonorrhœal salpingitis, and why should we not have tubercular salpingitis? He does not think that salpingitis occurs from gonorrhœa as often as some would have us believe; it is more often from abortion and parturition.

Dr. W. T. Howard, Jr., said that the work of Dr. Williams had raised an affection of supposed rarity to one of more common occurrence.

The Relation of the Organs of Reproduction to Cerebro spinal Disturbances in Women.—This was a paper by Dr. T. A. Ashby. Perversion of the psychical centres is often due to menstruation, conception, etc. There is a close connection between the nervous system and the genital organs. These reflex disturbances are physiological within certain bounds. Lacerations of the cervix uteri are a frequent cause of nervous irritation. These neuroses frequently disappear with great promptness when the cervical tear is repaired. Oöphorectomy is often performed for excessive nervous excitement.

Dr. George J. Preston was glad to see Dr. Ashby take the conservative stand in a place where conservatism is so necessary. We have perhaps gone too far. A woman likes to have some place to put the cause of her nervous feeling, and the most natural place is to refer it to the reproductive organs. Pathological conditions of these parts will exert an influence on the higher centres. This is a complex reflex. The nervous system is also unstable, and this is the beginning of the trouble. The good of an operation may be often due to the effect on the mind, the rest, the quiet in bed, and not so much to the operation itself.

Dr. J. Whitridge Williams said that unless some pathological lesion could be found the operation was unnecessary. It was almost a question of malpractice when it was done without finding a lesion. A careful examination by bimanual palpation, under an anæsthetic, will enable the skilled gynecologist to make an accurate diagnosis before operation. From recent investigations by

himself and others, it was very probable that a large part of the ovary was composed of nervous tissue, and it was natural that such an organ should produce these nervous symptoms.

Dr. W. E. Moseley said that many a grave pathological change will cause no nervous symptoms, and many of the worst nervous symptoms are produced without pathological change. The influence of the lacerated cervix on the nervous system is most marked. He did not believe the moral effect of an operation is as great as some would have us believe.

Dr. A. K. Bond said that, looking at the subject from the standpoint of the general practitioner, many cases came for treatment too late. Many cases remain untreated too long, and then get into the hands of the gynecologist because the nervous symptoms were untreated. If these nervous symptoms were treated early they would yield, and the patient would get well without going to the gynecologist, who straightway proceeds to make an examination.

Dr. Robert T. Wilson did not think that the conscientious gynecologist would do this unless absolutely necessary.

Dr. Bond replied, then her friends would send her to another who would do it.

The Radical Cure of Hernia, was the title of a paper by Dr. W. S. Halsted. This is a very important operation. Most reputed radical cures are not cures at all and recur. In the sixteenth century, if taxis failed the patient died. The literature of the subject is very full. Paré, in the sixteenth century, wrote of it and tried to find a cure. At the end of the last century it was more generally understood, and operations were more frequent. Sir Astley Cooper has written the best work on it. All these operators showed great respect for the arteries, but in many respects the manner of performing the operation was about the same as now. Macewen's operations were an advance, but they were not successful. McBurney has done the best work in this country.

In 81 cases, at the Johns Hopkins Hospital, the speaker had operated on 59 by ligating many of the veins and transplanting the cord so that it is outside of the sheath and subcutaneous. The mortality is nothing. Bassini's results, on a much larger number of cases, were about the same. In 17 of his cases the hernia had not returned in two and one-half to three years, and in 42 from six months to two and one half years. A case can hardly be called cured unless it has remained well for three years or more, since many cases recur.

Some Minor Therapeutic Uses of the Galvanic Current.—This was a paper by Dr. A. K. Bond. His work had been done with the dry chloride of silver battery, and consisted of simple galvanization, cataphoresis, styptic, electric knife, electric sound, and cauterization with the electric needle.

Operation for Removal of a Peach-stone Lodged in the Œsophagus, was the title of a paper by Dr. J. M. T. Finney. It was a very difficult operation. The stone was so lodged that it could not be pushed down, and even when the stomach was opened it could not be pulled out of the œsophagus with the fingers. A sponge attached to a string and passed down into the stomach dislodged the stone. The wound was sewed up and healed. Later an abscess appeared in the spinal region, but was opened and the patient finally recovered.

Localization of Tumors of the Brain.—This was the subject of some remarks by Dr. George J. Preston. Brain tumor is more common than was formerly supposed. It occurs at all ages and in children. Men are more liable to it than women, from traumatism and syphilis. The diathetic tumors include the syphilitic and the tubercular. The sarcomatous include the sarcoma and glioma. We have also the psammoma. The diagnosis must be exact. Brain tumors have aided us in the localization of the brain functions. Prolonged, continuous, and intense headache is always suggestive of tumor. Localization of pain is of no diagnostic value, but tenderness on percussion is of great help. Other symptoms are vomiting, vertigo, neuritis, and optic atrophy.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE GROCERS' COMPANY AND SCIENTIFIC RESEARCH—DR. WILLIAM HUNTER ON THE PHYSIOLOGY AND PATHOLOGY OF BLOOD-DESTRUCTION—A SUCCESSFUL CASE OF RUPTURED HEPATIC ABSCESS—THE RADICAL TREATMENT OF SEVERE EQUINO-VARUS.

London, November 26, 1892.

Numerous attacks have been made within the last few years upon our great city companies and the administration of their large funds. Some of the companies have done much to disarm criticism by making generous contributions to various philanthropic and scientific objects. The Grocers' Company is foremost among those which have liberally donated in this manner. Some years ago they enabled the authorities of the London Hospital to add a new wing to their building by handing over to them a donation of several thousand pounds. More recently they have devoted some of their funds to endowing scientific research. Dr. William Hunter, Assistant Physician to the London Fever Hospital, was lately one of their research scholars, and a few days ago he commenced a short course of lectures, in which he gave an account of his investigations into the physiology and pathology of blood-destruction. In commencing his first lecture he observed that the literature on the subject was of the scantiest, and that no paper had hitherto dealt with the subject in a systematic way. The activity of the other tissues was so bound up with the condition of the blood that it was a matter of paramount importance to learn everything we could respecting it. The slightest deviation from the normal at any period might carry with it results out of all proportion to the apparent magnitude of the change itself. The lecturer said he regarded the blood as a highly organized tissue—one to which he would assuredly apply the term "living" did he not fear to be asked to define what life was. The relations of the various parts of the blood were, if less close anatomically, no less intimate physiologically and chemically than those of the cells and matrix of any other tissue. In the case of the plasma and white corpuscles the evidence of blood-destruction that we possessed was comparatively slight. The case was different with the red corpuscles; evidence of their destruction (hæmolysis) was afforded by a study of bile and blood-pigments. As regarded bile-pigment the evidence was of two kinds—that pointing to hæmoglobin as its source and that pointing to the liver as the seat of its formation. The crystalline pigment (hæmatoidin) frequently found in old extravasations of blood was chemically identical with bilirubin, the chief pigment of bile, and some of the pigments giving rise to the discolorations of bruises were indistinguishable from bilirubin and biliverdin. The genetic relationship between hæmoglobin and bile-pigment became clearer still when we considered the close connection between increased destruction of hæmoglobin and increased formation of bile-pigment; when hæmoglobin was injected into, or set free within, the blood, an increased excretion of bile-pigment in the bile ensued.

Since blood-pigment, wherever found, indicated death of red corpuscles, he had endeavored to ascertain under what conditions and in what situations it was normally to be found. He excluded from consideration pigment arising from extravasation or chronic congestion. He had made observations on rabbits, guinea-pigs, dogs and cats, ducks and pigeons, and on frogs, as representative of the classes of herbivora, carnivora, birds, and cold-blooded animals respectively. He had found blood-pigment in

the liver, spleen, and the red bone-marrow, occasionally in the kidney. Within the liver blood-pigment was found in two situations, viz., the capillaries and the liver cells. Pigment in the capillaries was usually distinguished by the large and varying size of its individual particles. The amount varied much in different animals and under different conditions. The chief factors influencing its presence and amount were: 1, The size and shape of the animal's red corpuscles; 2, the age of the animal—the pigment increasing with age; 3, diet and exercise—abstention from food and exercise increasing it; 4, certain pathological conditions might increase it, but not constantly, even with the same animal. The frequency with which pigment was found within the liver cells differed in birds and mammals respectively. It was usually found in the former and sometimes in large amount; in mammals it was either absent or only present in small quantities. Pigment-granules in the cells were uniformly small, while in the capillaries they were much larger and of varying size. Neither the amount nor the character of the granules was influenced by such factors as size and shape of the red corpuscles, old age, abstention from food and exercise—all of which influenced the amount of pigment within the capillaries. The only respect in which the conditions were the same was that in both cases a large increase in the amount of this pigment might take place in disease, or might be induced experimentally by the action of agents which destroyed the blood; the increase which might take place under such circumstances within the liver-cells was, however, not only more frequently met with, but was, with few exceptions, much greater than anything ever observed in the capillaries. Whatever favored the slow and gradual death of the red corpuscle, or its death as a whole, favored the presence of pigment within the capillaries to the exclusion of the liver-cells; whatever favored its more rapid destruction and its complete disintegration favored more its presence within the liver-cell, although not there exclusively.

The spleen was a favorite seat of pigment accumulation—apart from extravasation or congestion. The variations of its amount in disease were less striking than those observed in the case of the liver. A third seat in which a certain, though usually very small, amount of pigment might be found in health was in the large marrow-cells of red bone-marrow. Pigment might also be found in the kidney, though the only condition in which he had found it was pernicious anæmia.

What significance were we to attach to the pigment thus present? It had hitherto been usual to regard blood pigment (always, of course, apart from extravasation or congestion) as an indication of some previous destruction of blood. Its presence, however, even in large amount, might denote a lessened hæmolysis; conversely, its absence was not only compatible with, but might actually point to a greater and more extensive hæmolysis. There were two distinct processes in the blood leading to the formation of blood-pigment—one invariably doing so, the other occasionally and not necessarily. The first was marked by a slow decay of the red corpuscle, and its death and inclusion as a whole within the body of active cells such as those of spleen or marrow, or the leucocytes of the blood; the peculiar feature of this process was that the whole of the hæmoglobin was invariably converted into blood-pigment. The pigment thus formed was that which we found within the capillaries of the liver—never within the liver-cells. The other process was marked at the outset by a liberation of the hæmoglobin from the red corpuscles, either alone or in combination with part of the stroma of the corpuscle. The hæmoglobin thus escaped into the plasma of blood or spleen might be taken up by active cells, but its usual fate was to pass into the liver cell and be there broken up—the chief results of this being the formation of bile pigments and the excretion of a certain small amount of free iron in the bile. Formation of blood-pigment need not necessarily attend this destruction of hæmoglobin within the liver-cells. Blood-pigment had a very varying significance as an indication of hæmolytic charge. The process that led to the formation of most blood-pigment, viz., slow death of the red corpuscle, affected only the red corpuscle, and implied, indeed, an absence of charge in the plasma; such a process could not be termed "hæmolysis." The other process was the only one which could be rightly thus termed, as it was marked by changes in the plasma and leucocytes as well as in the red corpuscles. Yet it was this process which favored the disposal of hæmoglobin in ways which might leave no trace of blood-pigment behind. The conclusion was that hæmolysis was a process which might be unattended by the formation of any blood-pigment; it followed that the absence of such pigment in health, as was the case in young mammals, was quite compatible with the occurrence of a very considerable daily hæmolysis. What was the extent of the destruction of blood in health? The close relation between hæmoglobin and bile-pigment was presumptive evidence of a certain daily destruction of hæmoglobin, and a large body of evidence pointed to the liver as the seat of conversion of hæmoglobin into bile-pigments. There were reasons for believing that it was within the liver-cells themselves, and not in the capillaries, that hæmoglobin was thus transformed. This conclusion carried the further one that whatever hæmoglobin was daily broken up to form the bile-pigments must have escaped from the red corpuscle into the plasma, and thence passed into the liver-cell. In other words, some degree of active hæmolysis was an event of everyday occurrence.

At the last meeting of the Medical and Chirurgical Society Mr. J. W. Hulke reported a case in which a large liver abscess (which had previously emptied itself through the lung) burst into the peritoneal sac. There was extreme collapse, but on the second day afterward the peritoneal sac was opened, a large quantity of pus evacuated, and the sac flushed out. The patient recovered.

Mr. Edmund Owen read a paper on "The Radical Treatment of Severe Talipes Equino-Varus," in which he advocated for severe cases the adoption of the operation introduced by Dr. A. M. Phelps, of New York.

WHY THEY DO NOT PAY.

To the Editor of the Medical Record.

Sir: In a recent editorial the lack of business qualities is made one of the principal reasons why physicians fail to receive proper remuneration for their services. This may be true in some instances; but the fact remains that, as a rule, the public discriminate unfavorably toward the physician as well as toward the clergyman.

With many the last claims to be met are the pewrent and the doctor's bill.

Many who are strictly honest, and will pay eventually, will say, when they meet their family physician, "Doctor, I am coming around to see you pretty soon; I have paid every bill I owed this year except yours."

In some cases prompt payment may be insisted upon, and even enforced by legal proceedings; but most practitioners have a large proportion of patrons who are exempt from legal process, a privilege they are not slow to take advantage of.

And this they will continue to do so long as our laws for the collection of debt remain unmodified.

Among them are men wearing good clothes, and smoking good cigars; some of them, in our churches, are exhorting their fellow men to lead pure and honest lives; others, if we may believe their eulogies, are walking the "golden streets" and sounding the "golden harps," but they owe us just the same.

Among the working-classes the idea is quite prevalent that every physician, after a few years' practice, must be very wealthy, and his services should be given to them

gratuitously, or, at least, that it is no crime to refuse to pay him, as the following case, in the knowledge of the writer, illustrates:

A farm-hand was ill with typhoid fever, and faithfully attended by a physician. When he was convalescent his employer said to him: "I will pay you for the months that you have been sick, and, if you wish, a month in advance, as you will have to pay your physician." "Oh!" was the reply, "I am a poor man, I don't think I ought to pay the doctor anything."

It has been said that when the physician receives no other remuneration he has the consciousness of having relieved suffering humanity and gained the gratitude of his patients. But, unfortunately, we hear more of gratitude in theory than we see in actual practice—a quality receding as convalescence advances.

"Three faces wears the doctor—an angel's when sought,
And a god's—the cure half wrought;
But when, that cure complete, he seeks his fee,
The Devil looks, then, less terrible than he."

A kind-hearted physician may attend an indigent family, for years, without hope of fee or reward; but let the tide of fortune turn with them, and a competency become theirs—will they continue to employ him? Oh, no! They will employ one who lives upon a more aristocratic street and has a liveried coachman. They "do not like to employ a physician who attends so many poor families," and, with a shrug of the shoulders, intimate that they have a very poor opinion of his skill.

These views may seem rather pessimistic, but they are facts easily proven.

The representatives of the healing art are, very properly, dispensers of charity; even the brightest lights in the profession give services, gratuitously, to the most abject pauper. But so long as they are devoting their lives to the interest of medical science, and to the amelioration of the sufferings of the human race, so long will they fail to receive prompt and cheerful remuneration for their services. Human nature is a paradox.

MEDICUS.

PHYSICIANS' ACCOUNTS.

To the Editor of the Medical Record.

SIR: In the line of your recent editorial upon the slack business methods of many physicians, it may be worth while to add that much of their slipshod way of keeping accounts is doubtless due to the comparatively recent practice of using one or the other of the labor-saving methods instead of such as are in vogue among merchants, manufacturers, financiers, and, indeed, nearly all other business men the world over.

The number of physicians who have not the time to keep a set of account-books by the ordinary method of single entry is comparatively small, and there can be little doubt that its adoption would cultivate an attention to methodical details which would result in the saving of many dollars.

The ready methods so generally used by physicians provide no facilities for keeping an account of income from other than purely professional sources. Few, I believe, attempt to keep a record of their expenses of living or their income from investments other than such data as are contained by a bank-book of deposits and the stubs of their check-books; and the making of an annual balance-sheet which will show the profits and losses during the year is most rarely undertaken, unless it happens that the physician is the executor or trustee of property belonging to other persons.

With regard to the legal value of physicians' accounts as ordinarily kept, it may be stated that courts have usually refused to accept the customary visiting lists and such hieroglyphics as are used to indicate the nature and date of professional service, as proper evidence thereof, but have demanded that a book of original entry, in the form of the day-book in commercial usage, specifying the nature of the service and the charge therefor in a manner that can be understood by a jury without the aid of explanations, should be produced.

Many physicians who have acquired sufficient property to yield a comfortable support for themselves and their families when they are aged will be found to have had a training in commercial pursuits before becoming physicians, and thereby acquired methodical habits of keeping accounts, which have contributed to, if, indeed, they have not been the chief cause of their prosperity.

If, upon commencing practice, young men could be impressed with the importance of looking after their accounts with the same care that they would use if they were engaged in mercantile pursuits, and of adopting the same methods as those which business men have found by long experience to be most desirable, we would less often hear of those who reach old age in comparative poverty in spite of years of painstaking and arduous professional labor.

Yours, etc.,
F. A. CASTLE, M.D.

NEW YORK, December 5, 1892.

RIGIDITY AFTER DEATH FROM STRYCHNINE.

To the Editor of the Medical Record.

SIR: In your editorial on strychnine poisoning by one Cream in England, in the issue of November 19th, it appears to have been claimed "that a person poisoned by strychnine would be after death preternaturally rigid, and there was a suggestion that that rigidity would be more or less permanent."

In January, 1888, I saw a body some hours after death from having taken at least ten grains of strychnine, and to my great surprise there was a total absence of rigidity of the body, because I had previously noticed preternatural rigidity in the dead bodies of dogs and cats poisoned by strychnine. Shortly afterward I noticed in Wharton and Stille's "Medical Jurisprudence" that convulsions may not be produced by a very large lethal dose of strychnine, the fatal result being in the nature of a shock to the nervous system. In the case to which I refer there was no history of convulsions prior to death, and there was no rigidity after death; so that there may be some relation between convulsions before and rigidity after death.

At the same time I saw another man suffering with spasms of moderate intensity from the effects of the same poison. He recovered.

JOHN P. WALL, M.D.

TAMPA, FLA., November 21, 1892.

THE DEATH-RATE OF CHICAGO.

To the Editor of the Medical Record.

SIR: The communication relating to the health of Chicago in your issue of November 26th, if it was really written seriously, and not as an over-statement intended to injure the cause it seems to favor, suggests some comments. By the "cause it seems to favor" I understand a local feeling against the city mentioned, that apparently exists in some parts of the country.

To believe that Chicago is a pestilence-breeding place, dangerous to pass through, which increases the death-rate for fifty miles around it, seems to me much more unreasonable than to accept the *prima facie* evidence of its mortality statistics. The writer of the communication also seems to be unaware of the fact that Chicago has annexed the most of its suburban villages, and that their statistics are included in its own.

As to the "poisonous water-supply," I do not believe that it exists at the present time, or that the inhabitants of Chicago, drawing their water from four miles out in Lake Michigan, run any greater risks than do those of other towns who imbibe the drainage of the inland ba-

sins of small streams. The conditions of last May and June were altogether exceptional, and even should the floods be repeated they could not reproduce the then existing state of affairs.

It also seems strange, to one who has by travel or residence had opportunities for comparison, to read of the "poor and expensive food-supply" of Chicago. I need say nothing as to its reputation as one of the greatest food marts of the world.

Undoubtedly Chicago has many sanitary deficiencies, but it has also some decided advantages, and that its rate of mortality should be low is not at all impossible. It certainly seems wrong for anyone to state or insinuate that its authorities send out falsified statistics, unless he is prepared to support the charge with adequate proof.

H. M. BAUMSTER, M.D.

HARLTON, CONN., November 29, 1892.

THE SANITARY CONDITIONS OF CHICAGO.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In a recent editorial you ask, "Why does Chicago announce so low a death-rate?" I have lived in Chicago most of the time since it contained but twelve thousand inhabitants. I have carefully studied its conditions, and it is clear to me why it does. I know no large city so favored by nature in its sanitary surroundings. Those who believe in special providences might be pardoned for thinking that when the foundations of the earth were laid the necessities for a great city here were foreseen and a fitting site for it provided. It was given a rude, but excellent climate; we grumble a good deal about it—as we are apt to do about everything we do not pay for—but it is very invigorating. It is conceded that the inhabitants of Chicago have shown great energy. This is not due to its people so much as to its climate. A muscle apparently dead will contract under the stimulus of an electric touch. Men could not breathe the air of Chicago without showing some signs of life and vigor. The city is situated on an extensive plain, with no confining elevations near it. The winds sweep through its rectangular streets from across the pure waters of Lake Michigan and over surrounding prairies from which malarial poisons are not exhaled. Intermittent disease is almost unknown in Chicago. Gases that must escape into the air from the streets of every city are speedily carried away by this ventilation of nature. The city stands so near the level of Lake Michigan that no dwellings are built in the ground. The poorest of its people are obliged to live in the sunlight and breathe air that is unconfined. While our water for drinking is not ideal, it is not bad, and most of the time it is good. It is true some of the sewage of the city is now discharged into Lake Michigan, but we receive our water through two tunnels under the lake, one opening two miles and the other four miles from the shore, and ordinarily beyond the reach of any outflow from the mouth of the river. Most of our sewage is emptied into the Chicago River, from which the larger portion of it is pumped into the Illinois & Michigan Canal, through which it is emptied into streams that carry it to the Gulf of Mexico. Free dilution and oxidation in the open air soon destroy its noxious qualities. This outlet by the canal will be enlarged to the capacity of a river. The city has provided for this purpose a fund of more than twenty millions of dollars, the contracts are let, and the work is in progress, with the promise that it will be completed in four years. Intercepting sewers will convey all the sewage of the city into the river and its waters will at all times flow into the Gulf of Mexico. This work is primarily undertaken for sanitary reasons; though doubtless it is influenced somewhat by commercial considerations, for when completed it will enable the shipping of the Mississippi and its tributaries to enter the lakes, and give to that river a second commercial mouth at Chicago.

EPHRAIM INGALS, M.D.

34 THIRD STREET, CHICAGO, ILL.

"THE INTRODUCTION OF ANÆSTHESIA."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your issue of December 3d is more than usually interesting by reason of the learned paper upon "The Achievements of American Surgery." In that portion of his paper devoted to the subject which forms the caption of this communication, Dr. Dennis remarks, "Morton, *at the suggestion of Dr. Jackson*, anæsthetized a patient on October 16, 1846, while Dr. J. C. Warren removed a tumor from the patient's neck." (Italics mine.)

Dr. Dennis has fallen into an error in saying that "Morton, at the suggestion of Jackson, anæsthetized a patient," etc., if by this statement we are to infer that this alleged suggestion influenced Morton or contributed to the introduction of anæsthesia, and I am sure he will pardon me if in a communication otherwise so just and uncontroversial I point out what seems to me an inadvertence. In making an obvious effort to be impartial Dr. Dennis has, in the single point I refer to, that of the suggestion, placed Dr. Morton in a light wholly inconsistent with the facts.

It is universally conceded to-day that the operation above referred to initiated the immediate practice of surgical anæsthesia throughout the civilized world. Morton stood alone at that critical moment in an amphitheatre of doubters, audience and surgeons alike. Upon him would fall the ridicule and the obloquy, if not also an indictment for manslaughter, in case of failure. But happily the operation was painless; anæsthesia was demonstrated and published to the world. It is little known that prior to this demonstration and Morton's first publication not one word had ever appeared in print on the part of those who afterward claimed to be "discoverers." Their relations to the discovery were *ex post facto*, their thoughts after-thoughts, their sight hindsight, their position that of would-be "jumpers up behind." Ingenious and pertinacious were their efforts to get a footing. The most ridiculous of these attempts is probably the claim of Jackson, based upon his remark of "Why don't you try ether?" and the further claim that he suggested to Morton to go to the hospital. Neither suggestion was of value to Morton. Several men had tried ether already and failed. As Sir Benjamin Brodie said when the discovery was announced, "I have heard of this before. I have tried it on guineapigs and it killed them. The question is, Is it safe?" Three months prior to this "try-ether" remark Morton proves that he had been buying large quantities of sulphuric ether from the druggist, Metcalf, and had consulted Metcalf & Wightman about its properties. But why did not Dr. Jackson try ether himself? "Did you make one little experiment?" said the late Professor Louis Agassiz to Jackson at a meeting of the Boston Academy of Arts and Sciences, adding, after receiving a negative reply, "It would have been better if you had." On another occasion Professor Agassiz said to Jackson, "If Dr. Morton had killed his first patient would you have accepted the blame as you now ask for the honor?" Dr. Jackson remained silent. And why did Jackson not go to the hospital and administer the ether? But he was not even aware that Dr. Morton had asked Dr. Warren for a public test, and he had never witnessed an operation under ether until a month after anæsthesia left the Massachusetts General Hospital, an accomplished fact. A week after the crucial operation at the hospital he was thus interrogated by the Hon. Caleb Eddy: "Dr. Jackson, did you know at such time" (October 16th) "that after a person had inhaled ether and was asleep, his flesh could be cut with a knife without his experiencing any pain?" He replied, "No, nor Morton either; he is a reckless man for using it as he has; the chance is he will kill somebody yet."

These and many more facts of the same tenor, supported by affidavit, have not the true ring of discovery or important participation in discovery on the part of Jackson. His whole story was the ingenious fabric of a para-

noiac, who successively claimed discovery after discovery of others, notably that of the electric telegraph from Morse, only to fail, as was most natural, to substantiate any real claims for credit in any of them. His obvious and final years of insanity, sad and deplorable as they were, offer the only creditable explanation of his position in the introduction of anæsthesia.

Long, in 1842, went far beyond Jackson, he tried ether—and failed; his patient was, it is true, "under the influence of an anæsthetic," as Dr Dennis says, but only so far under it as the self-inhalation common to the "ether frolics" then in vogue would produce—a stage now recognized as primary anæsthesia, a momentary peripheral numbness of the skin. Venable, the patient, says of this operation: "I continued the inhalation of the vapor until the operation was over," "I felt a little pain," etc. Had Long seized the towel and forced the etherization, the discovery might have been made then and there.

Wells also tried nitrous oxide gas and failed. Even after the demonstration of ether anæsthesia in 1846, so late as 1847, Dr. Wells repeated his Boston experiment (a failure) in the amphitheatre of the New York Hospital, before Mott, Francis, Parker, Van Buren, and others, and again absolutely failed. Evidently nitrous oxide anæsthesia, as Wells understood it, did not work. Others solved the problem, and that not until 1863.

The efforts of Long and Wells left no sequence—neither they themselves, nor others, could repeat such success as they had—the world was no happier for their efforts, there was yet no practice of anæsthesia.

And while it is well to accord all possible credit to Long and Wells and Jackson, it is yet just to recall that Morton stood, self-reliant and alone, at the first public demonstration of that discovery, which by strange contrast a young and industrial nation like America contributes as her quota to the relief of suffering humanity, a contribution which it is safe to say will be last to be celebrated, if celebrated at all, at the approaching Columbian Exposition.

Dr. Dennis further refers in kindest spirit to the "tragic termination of life in the case of Jackson, Morton, and Wells," the former, and probably the latter (at least it is kindest to believe so) dying insane, and Morton dying "without worldly means." Is it not perhaps more tragic that he should be allowed to so die by a Government who filched his discovery in its great war, by a public who absorbed it without recognition, and by a profession who, individually, the world over, make profit out of it daily.

Yours, very truly,

WILLIAM JAMES MORTON, M.D.

NEW YORK.

Medical Items.

Cholera in Paris in 1892.—Our correspondent in Paris writes under date of November 22, 1892: "The impression being quite general that the Paris authorities concealed the real state of the cholera epidemic in that city, it may be of interest to the readers of the MEDICAL RECORD to know the facts. Paris being the great pleasure city of the world, and having at all times a large floating population, there is no doubt but what, at the outset, the authorities and corps médical in general made light of the disease, and quieted the anxiety of any inquiry with the assurance that it was not Asiatic cholera, and was sporadic in character.

"From the *Bureau de Statistique municipale* I have obtained the weekly reports for the past year, from which I have taken the *résumé* of the history of the disease from its beginning to the present date.

"The first intimation of the disease appears in the report for the week ending May 19th, seven deaths, under the simple heading of Enteritis or '*Diarrhée cholériforme*,' without comment. In the report for the week ending May 26th appears: 'There were three deaths from *Diarrhée cholériforme* or *Choléra nostras*, which is not called epidemic, as there are a few cases in Paris every summer.' A foot note to this report informs the public that the municipal authorities send for, disinfect, and return free of charge, all objects and effects pertaining to cases of contagious diseases. June 9th, reports six deaths in Paris and three from the neighboring suburbs. June 16th, four in Paris and four from the suburbs. June 23d, four in Paris and seven from the suburbs, of *Diarrhée cholériforme*, *Cholérine*, or *Choléra nostras*. June 30th, five in Paris and eight from the suburbs, of *Cholérine*, *Choléra*, or *Choléra nostras*. July 7th, four in Paris and four from the suburbs, from the same causes. July 14th, fourteen in Paris and eighteen from the suburbs, and of which part are ascribed to cholera asiatica. July 21st, there is simply noted, under the head of diarrhœa, fifteen deaths in Paris and twenty-nine from the suburbs, of persons over five years of age. July 28th, fourteen in Paris and fifteen from the suburbs attributed to diarrhœa. August 4th, twenty-one in Paris and eleven from the suburbs under the same head. August 11th, seventeen in Paris and seven from the suburbs under the same head. August 18th, is noted as follows: 'The deaths from diarrhœa are diminishing; there were twelve in Paris and only two from the suburbs during the last week.' August 25th, appears 'The diarrhœal diseases caused twenty-two deaths in Paris and two from the suburbs, this week.' During the week ending September 1st, there was a large augmentation in the number of deaths, and they are noted under a separate heading as *Affections cholériformes*. One hundred and twelve deaths in Paris and ten from the suburban districts. From this date the deaths are recorded daily under the heading above mentioned. September 8th, for the week, one hundred and seventy-seven in Paris and twenty six from the suburbs. A foot-note again calls attention to the free disinfection by the city authorities, and reports seventeen hundred and thirty such disinfections made during the month of August. September 15th, one hundred and forty-eight deaths in Paris and forty-two from the suburbs. September 22d, seventy-one in Paris and seventeen from the suburbs. September 29th, sixty-four in Paris and fourteen from the suburbs. October 6th, sixty-three in Paris and sixteen from the suburbs. October 13th, thirty-two in Paris and thirteen from the suburbs. October 20th, seventeen in Paris and seven from the suburbs. October 27th, four in Paris and two from the suburbs. The city authorities were applied to for free disinfection in two thousand two hundred and ninety-six cases of contagious diseases during the month of September. November 3d, four deaths in Paris. November 10th, four in Paris. November 17th, no deaths in Paris, and only one from the suburbs.

"The cases noted as from the suburbs, are persons taken with the disease outside the walls of the city, who were transferred to, and died, in the city hospitals. As will be noticed, the figures given are for each week, and considering that Paris has two and a quarter millions of inhabitants, the disease cannot be said to have reached the extent of an epidemic, and was at all periods well controlled; and with its peculiar civic and medical governments, and the most wonderful sewage system of the world, an epidemic of cholera is little to be feared."

The Latest Cholera Story.—A stranger arriving in Paris the other day, says the *Daily Graphic*, was accosted at the station by a man who stated that he was a sanitary agent. "Have you been disinfected?" he asked. "No," replied the traveller. "Very well, then, follow me." And the "sanitary agent" led the way to a house in the rue Lafontaine, near the station. At his bidding the traveller entered a large bare room and took off all his clothes, which were taken away to be disinfected. Time passed; the traveller grew cold and impatient, tried the door, only to find it locked, and at length realized that he was the victim of a new and ingenious form of robbery.

PRECISION IN THE TREATMENT OF CHRONIC DISEASES.[1]

BY S. WEIR MITCHELL, M.D., LL.D.,

HONORARY FELLOW OF THE NEW YORK ACADEMY,
PHILADELPHIA, PA.

GENTLEMEN: I have twice, to my regret, been obliged to decline requests to speak before this learned body, and lest I might seem to you ungracious, I have come hither now asking the privilege of which I had twice been unable to avail myself. Perhaps, ere I am through, you will be sorry that I did not add another to the number of my refusals. I ask you, beforehand, to pardon me if I speak, as I must, on some familiar points, or if I too often refer to my own work. If I am discursive, and wander over a variety of subjects, this, also, you must charitably excuse.

A part of the difficulty in effectually securing the attention of the best of the mass of our profession, lies in the fact that to do this a busy man must go on insisting in too frequent writings upon the value of any new drug or method. As we of necessity use the journals to do this, what is said does not always reach a complete or fit audience. This applies largely to our American journals, which are quite too numerous, and which very often note in a hasty paragraph what ought to be elaborately stated, when it is a method or plan which is urged, and which, if it needs to be at all understood, needs to be stated with care. We only share, I grieve to say, in the malady of haste which afflicts our literary journals. A flood of hasty statements, or of mere brief notices of new books, to-day constitutes in our general literature what, with easy indifference to the meaning of the word, we call criticism. The grave, well-considered reviews of former days, such as are still seen in France and England, and are apt to be the pleasant product of the leisure of thoughtful scholars have ceased to exist for us. Only in our great dailies have we competent and elaborate reviews. Our medical literature has suffered a like unpleasant change. Brief statements as to new books, new drugs, new methods, succeed one another in our journals with bewildering speed. One misses the grave scholarly estimates common in other days; the accurate, large-minded handling of a whole subject by men of rank and esteem in the profession. A medical journal is apt to look nowadays like an advertisement fence with hurried graphic *affiches* of the latest novelties. In this rush of equality of setting forth of the good and the bad we run some risk of not soon enough comprehending the more troublesome, and yet more valuable methods. Soon or late they win; for our great jury in the end is seldom wrong. I somewhat suspect that the numberless new drugs may a little have set us back in medicine, by offering so much to distract attention from the surer methods of general management in chronic disease.

No doubt there is a look of implied simplicity in the temptation to slay disease with a triple daily discharge of a promising drug; and how very promising the drugs are just now, and the journals, and the covers of the journals! It is a therapeutic fairyland. More natural means and more slow methodical management are apt to be set aside. They win no easy hearing. I have had many illustrations in my life-work of these passive and active obstacles in the way of teaching men new ideas, when these were troublesome, because accurate and carefully elaborated.

As I have been asked abroad and at home, over and over, to speak on the subject of the treatment which in Europe is known by my name, and here as Rest Treatment, I may assume either that it is not yet fully understood, or that I am presumed to have made in it further changes worthy of attention. I have, however, little to add. Its origin and history might be worth telling had I the time.

Yet something remains to be said as to those who use or misuse the method in question. My desire to speak as to this text is justified by the debate which took place upon Rest Treatment last year in one of your own societies. It then became clear that not all who assumed to use it had read my book, and that others failed to apprehend in it a systematic procedure, which involved the regular doing of several distinct things, scarcely one of which could be left out at will without damage to the desired result.

As a contrast to this loose method of dealing with my work, let me call attention to the words of William Playfair. He says: "I have used this treatment freely; I have nothing to add to it and nothing to subtract." The honor and fair dealing of such a statement strike one with pleasure. Of what one of your own members has said of it in a recent book I hesitate to speak. It has really given me new courage to bring this treatment before you to-night. I had supposed, indeed, that I had said my final word on Rest Treatment; but now I am tempted to think that in the way of insisting on its use, its complete use, there is still room for me to break my silence.

You all know what I mean by Rest Treatment. It is a final resort. Let tonics, change of air, exercise fail; let the gynecologist have said his last word, or, what is more likely, done his last operation; then comes this rather troublesome method. I avoid detail here. We put a person in bed, use massage, electricity, excessive feeding, and only at need, seclusion; forbidding letter writing, and in many cases for a time, reading. I continually hear of "modified rest treatment"—and a "kind of rest treatment;" and a physician says (and this is literal), "I have used all the details of rest treatment, but did not think it needful to keep the patient in bed." A doctor writes me, "Is massage really indispensable? Another, "According to the rules of your admirable treatment, I kept Mrs. B—— in bed five months, and now she will not get up at all. What shall I do?" Of course, men are free to leave out the part of Hamlet, but then I prefer that Ophelia be left out also, and naturally I object to this being called my treatment, and to being held to critical account for failures so caused.

I shall say presently what I think about certain reasonable variations upon rest treatment, but now I am thinking of the typical instances of emaciated, broken-spirited, hysterical women, or of exaggerated neurasthenia—rarely unmixed with hysteria—cases in which no one can afford to depart from the rules I have laid down and yet hope to succeed by this method, at least. It is with just such sick people that the invertebrate doctor is sometimes driven to compromise; he says, "Ah, well, my dear, you shall have all the treatment except rest in bed; I won't insist on that." Or the woman says, "I must have the dear children every morning." The physician

[1] An address delivered before the New York Academy of Medicine, December 15, 1892.

has not the courage to say, "I am not attending the children." So she has her way and the treatment fails. I, of course, prefer not to be made accountable for other men's moral or intellectual bankruptcies, or to be held responsible for the debts of indecision and weakness. Such men are like *Punch's* fashionable London physician. Says the Duchess, "Dear doctor, I could not think of it. What! cod-liver oil and whiskey!" "Certainly not, Madam. Shall we say curaçoa and cream?" But of course no one here has ever given way to this form of feebleness.

This is a treatment of detail, and just how you manage the minutiæ is of great moment. No treatment ever yet devised can be carried on without intelligent thought. The story of Sir Joshua Reynolds and the need an artist has to mix his colors with brains, has here its applications as elsewhere in life. The abler doctor lives above all text-books. He lives, too, above the mere fashions of his time in medicine. In the days of excessive bleeding there were Cardans, and later on Sydenhams, who knew when not to bleed, just as to-day there are among you those who comprehend that the lancet has still its place in medicine.

One sign of signal ability in the medical practitioner is the clear apprehension of the fact that, whatever the disease, it is an individual who exhibits and eternally modifies its phenomena. It is, too, the great men of our guild who never lose sight of detail in medicine. No patients so personally modify disease or its expressions as the nervous or hysterical; in no plan of treatment is success so entirely at the mercy of industriously perfected details of treatment, intelligently apprehended, and reasonably modified. Therefore is it that it is the best doctor, as a rule, who does best even with so definite a treatment as the one now considered. I have, indeed, known a clever woman to take the whole rest treatment with the aid only of my book and a maid. I have known nurses who had with brilliant success carried it through without a doctor. I have known very good physicians to fail, either because they lacked some moral quality, or because they slighted the details and left too much to nurse and rubber.

Let us linger over these a little. The nurse for rest cases needs a large amount of patient interest, power to distract or amuse, capacity to read aloud, tact and good-tempered cheeriness. It is a sharp test of character to shut up together for six or more weeks two women, and one of them ill and nervous. Divorce ought to be easy and ever ready. If you use rest treatment, question your patient early as to her nurse, and if she does not like her, even if in your eyes she is one of the best, it is wiser to give her up for another. I have had to change thrice in a week, displacing attendants who seemed to me good, and yet I won my battle at last. You cannot change the patient, you cannot change the doctor (how much one sometimes would like to do this!), but the nurse you can change.

Then there is the rubber, apt to be a gossip and to talk of cases. You will do well now and then to give a little time to watching her at her work. Generally the Swedes rub badly and without method; are fond of mere effleurage; or slap and pound the distracted, nervous woman into a condition of excitement. I have often been myself massèd in Europe, where such massage as rest cases need is ill understood. On the whole, it is far better done in this country. The American plan of muscle-kneading, carefully and systematically done with thought at the very finger-ends, is what we want. I am inclined to think one of the best tests of good massage is the power to rub out hard, inflammatory deposits left after repeated pelvic inflammation. In these cases I use the massage as often as thrice daily, and at the close, where there are weak muscles and relaxed ligaments, employ a system of resisted movements of the thigh and belly muscles. Why one woman can rub a patient and leave her sleepless, excited, uneasy, and another succeeds in soothing her and in calming her nervousness is even yet to me a problem which I can solve by change, but cannot understand. The early use of massage, the dosage of it as to time and vigor, need attentive care; after a week it takes care of itself, but rest assured that for folks who do not exercise there is no tonic to compare with it. The charges made for massage in New York seem to me excessive, but this is in your own hands.

There have been so few unfavorable comments on this method here and in Europe, that in looking over the many papers it has evoked, and the Prefaces to the translations of my book in German, Russian, French, and Italian, I find little to answer. Some have set aside the daily use of electricity as needless and expensive. It is the one thing you may omit; I do not advise you to do so. In some cases it leaves the extremities warm when massage does not. It is apt to create at first some nervousness; therefore, for two days at the start, the nurse (and all good nurses can use electricity in this simple form)—for two days, I say, I ask the nurse to let the battery act as usual and to employ the conductors in due form without allowing any current to pass. The patient thus gets accustomed to an unusual remedy, and if nevertheless she be thus excited or made nervous, can then be told that no electricity has been used, and that future nervousness must therefore be laid to the account of her own watchful anxiety.

And so as to drugs. These nervous people are afraid of drugs, or full of queer prejudices about them. If you give malt extracts (Wyeth's or Bass's are the best), they can be made to dissolve "that dreadful iron she could never stand," or be the unguessed carriers of mild and repeated aperients. I once had a too clever patient who declined to take arsenic or hyoscine, both of which I thought essential in her case. She asked the nurse if I had put either in the malt, but did not guess that the three oranges she took daily received each a hypodermatic injection of the two objectionable drugs. By and by, when she was mending, I told her, of course, and henceforth gave, in other and ordinary ways, whatever I willed to give.

I have elsewhere stated the modifications to which we may submit the treatment by rest. The most important has been elaborated and stated with care in Hare's "System of Therapeutics," by Dr. J. K. Mitchell. Its success is a fair illustration of the power for therapeutic good of a life conducted for a time on schedule. And here again you must pardon me if I urge in your treatment of chronic disorders something of the accuracy we all carry into the management of acute diseases. It is really more essential to write out in detail how a man should live in order to get over a chronic malady than an acute one, where nurse and doctor are ever at hand. Let the following schedule of what we call partial rest explain my meaning. We have to deal, let us say, with a case of moderate neurasthenia and insomnia, with or without dyspepsia. In a word, you are to treat a woman not ill enough to be put to bed, not well enough to be cured by mere tonics, or even by these with change of air. You all of you know these cases. What I propose is to ask this patient to live by schedule, which may be modified to suit the case. I shall not read the too elaborate details, but I shall ask you to accept as exemplars copies of the typical formal scheme, which in every such case I have written out with care, because in many of its details it must vary with the patient. Remember it is not for a doctor, but for the patient.

Schedule for Partial Rest Treatment.—A.M.: On waking, cup of cocoa. Take bath. (Temperature given.) Lie down on lounge while using drying towels; or better, be sponged and dried by an attendant. In this process the surface to be rubbed red, or, if drying oneself, to use flesh-brush. Bed or lounge again. Breakfast. Before each meal take three ounces of malt extract; aperient at need in malt. Tonic after each meal. Detail as to breakast diet. If eyes are good, may then read seated in bed. At 10 to 11 A.M., one hour's mas-

sage. Rest one hour; may be read to, or read if eyes are good, or knit. At this time, 11 A.M., four ounces of beef soup or eight ounces of milk. At noon may rise, dress slowly, resting once or twice a few minutes while dressing, and remain up until 3 P.M. See children, attend to household business; see one visitor, if desirable. 1 to 1.30 P.M., malt, etc., and lunch. Detail as to diet. At first, as a rule, let this meal represent dinner. Tonic, and after it to rest on a lounge, occupied as above, reading or being read to. If possible, to drive out or to use tramway, so as to get air. Walk as little as possible. On return from drive repeat milk or soup. About 5 P.M., electricity, if used at all. Rest until 7 P.M. Supper at 7 P.M. Detail as to meal. Malt as before, with or without aperient, as occasion demands. Tonic. To spend evening with the family as usual. Best not to use eyes at night for near view. Bed at 10 P.M. No letters to be written for two months, when most of these details have to be revised.

After two months of massage it should, in these cases as in complete rest, be used on alternate days, and by degrees given up. If the nurse or masseuse is able to teach the patient the use of Swedish Movements, it is desirable that these or some definite, slowly increased system of chamber gymnastics be continued for months. Finally, walking must be resumed with slow and systematic increase. After the second month I write out a schedule of less restriction, to be followed for six months.

What I dread most at the start, in all cases for rest, is grave insomnia. Whether it be accompanied by a state of mild mental excitement, such as we all know, or is a pure incapacity to go to sleep, or to stay asleep; or whether it be in popular medical belief a congested state, I am apt at once, in bad cases, to use thrice a day lithium bromide, at first in thirty-grain doses, at noon, at 6, and 9 P.M., given in the malt or not, and soon decreased grain by grain. If I want a positive aid at bedtime, I prefer sulfonal in hot water. But of greater value are some of the hydro-therapeutic devices—and best of these is what is known, or not known, as the "drip-sheet." Just how this is to be given is of the utmost importance. The following memoranda, which I shall not read to you, but shall ask you to read hereafter, must answer to show how careful one must be, in my opinion, as to these details. I give it here in brief much as I do to a patient not under the immediate care of a nurse. I cannot help adding that several of the most useful of the water processes are neither taught in our schools, nor so accurately in hydro-therapeutic text-books as to be of much value to the general practitioner.

Memoranda for Use at Bedtime of Drip sheet.—Basin of water at 65° F. Lower the temperature day by day by degrees to 55° F., or to still less. Put in the basin a sheet, letting the corners hang out to be taken hold of. The patient stands in one garment in comfortably hot water. Have ready a large, soft towel and iced water. Dip the towel in this, wring it, and put it turban-wise about the head and back of neck. Take off night-dress. Standing in front of patient—the basin and sheet behind—the maid seizes the wet sheet by two corners and throws it around the patient, who holds it at the neck. A rough, smart, rapid rub from the outside applies the sheet everywhere. This takes but two minutes, or less. Drop the sheet, let the patient lie down on a lounge upon a blanket, wrap her in it, dry thoroughly and roughly with coarse towels placed at hand. Wrap in a dry blanket. Remove ice wrap; dry hair; put on night-dress. Bed, the feet covered with a flannel wrap.

If all this seems to you as you read it too absurdly minute, I shall feel some regret. Yet believe me, it is worth the trouble, and the drip-sheet a remedy past praise. If it fail, a pack may succeed; but this is more familiar to you. I doubt if the use of the drip-sheet is as well known.

Since rest treatment has taken its place in medicine, I, and others, have extended its use. In the treatment of chronic alcoholism rest in bed for a few weeks has obvious values, and, combined with skim-milk diet and massage, is often of use.

In all forms of neuritis, local or general, rest is essential, and in alcoholic neuritis, rest, massage, milk diet, and the use every three to six hours of what I may call cold and heat alternates, will often triumph rapidly This use of cold and heat is effected by putting the feet and hands in iced or very cold water a few minutes, and then applying in turn to each extremity the greatest heat endurable by mopping with soft towels dipped in nearly boiling water. The limb is then replaced in the cold water, and after three or more alternate uses of heat and cold is taken out, warmed well, and left dry.

Obstinate cases of chorea are best treated by rest, absence of friends and of all excitement, massage, and, of course, arsenic or what not.

Again, I treat all grave cases of morphia habit by absolute rest in bed. This alone has easily seen advantages. If the case be a very bad one, before I take away the drug I like to use for a time massage, very large doses of bromides, and to train the stomach, which is our worst foe, to endure a diet of peptonized food, preferably milk. The subsequent chance of escape with moderate suffering is thus largely increased, and when we are free from the more immediate consequences of laying aside the opiate, we easily return to normal diet. The common sense of all this must, I think, be clear to you, and some of what I have said is novel as well as useful.

My remarks in regard to neuritis lead me to say a few words about sciatica, which is nearly always some grade of neuritis. At least twenty years ago, I began to treat such sciatica by local splint rest with from two to three weeks of local use of ice, if rest alone failed me. Although I have over and over called attention to these means, they have not so captured professional confidence as I could desire. Last year I wrote on them a lecture in the International Series, where it is, I fear, pretty well buried amidst some good, and some poor, clinical lectures. As I have of late modified the treatment, and am sure from my own experience and that of Professor Osler, Dr. Sinkler, and others, of its great value, I beg to ask you to consider it with me anew. In any obstinate sciatica, where I can exclude spinal cord disease, constitutional states, tumors, etc., I put my case in bed. Then I give cod-liver oil, iron at need, full diet, and milk between meals. A long flannel bandage is put on at once rather tightly from the foot to the groin, and renewed twice a day. At the side of the limb a long splint is secured by a few turns of bandage. The splint should reach from axilla to ankle, the knee being bent a little, the heel secured from pressure. The splint and bandage are kept in place from two to four weeks, night and day; once a day, when these are removed, the leg is slowly and very moderately flexed and extended. This treatment is in constant use at the Infirmary for Nervous Disease. If it fails, it is usually because the malady is at first, or has become, spinal. The rationale of its use is, I think, clear. 1. The flannel bandage lessens the blood in the leg. 2 It protects the whole skin surface from the excitation of contacts. 3. The enforced immobility makes all motion impossible, and so the two uses of the nerve cease. It is in splint and we get physiological rest. Since I have used the bandage the cumbersome use of ice along the nerve-track is less often required. At the close of the treatment, massage, used with extreme care, may hurry the recovery. If there are persistent pain points, mild surface cautery may be employed at last, but for all details as to how to get the patient afoot and keep his gains, as to use of ice at need, etc.—in a word, as to all minutiæ which make for success (indeed, very frequent and permanent success), I must refer you to the lecture in question. I might have said far more, for, of the value of these means I am very sure, but I am talking to an audience of accom-

plished men, and I expect them to preach to themselves the sermons for which I but venture to furnish the texts.

This lecture has assumed the discursive character of a talk, and still relying on your indulgence, I venture to turn aside and ask your attention for a few minutes longer to some thoughts about pain, our constant foe, and especially to some forms of pain. I have often wondered why the great Being, who started us under certain laws upon the long career of reproduction, evolution, and self-modification, should have designed clearly a progress upward, and yet set in our way such limitations. We might all have had one eye for distance and one for near view; we might to some extent get on without the sense of pain; and that we could do with less of it is shown by the fact that some women remain for years without the pain sense. In one case of mine a hysterical paralytic recovered really useful health, and except herself and myself no one knows that she cannot be hurt by knife, or fire, or a blow. The interior organs still feel pain as usual. All other forms of skin sense are as keen as ever. This woman used to hurt or burn herself from want of care; now she has learned to take heed. I have seen many such, but only one other where the general health was as competent. She doubts now whether she would accept anew the natural condition of the pain sense. And do we really need it after it has served to give the educational sensory warnings of childhood? Once, says my patient, pain taught me to fear or avoid fire; now, warmth does this and suffices. The speculation is a curious one. I found by chance, of late, the following case of a man, said never to have known pain. The observer, Dr. Paul Eve, was fortunately a witness so good as to leave no doubt as to the truth of the statement. It is much to be regretted that this unique history should not have been more full.

Case of Natural Anæsthesia (Paul Eve's Surgical Cases, p. 771).—Dr. Eve says he knew the patient; for years he was intimate with his family physicians. They had often spoken of Mr. A——'s peculiar incapacity to feel pain. He became at last Dr. Eve's patient and died of erysipelas, apparently made worse by repeated applications of tartar emetic ointment, used by the sick man in excess because they gave rise to no pain. The remainder I quote in full.[1]

"Mr. A—— was about fifty-six years old at the time of his death. He was of sanguino-leuco-phlegmatic temperament; was a corpulent man, weighing about two hundred and fifty pounds, and had been a free liver. He was a lawyer by profession, of good intellect, being a man of strong mind and body, and had acquired considerable reputation as an advocate and politician.

"And now, in relation to his possessing a natural state of anæsthesia, the following facts are submitted: During a political campaign, not liking the appearance of a finger injured in a *rencontre*, he bit it off himself and spat it upon the ground. He had at one time an ulcer on a toe, which resisted treatment for nearly three years. Mr. A—— told his physician at the time, and has since repeated the same statement, that from first to last it never gave him any pain. An abscess also formed at one time in his hand, involving in its process the whole forearm and arm, which became enormously swollen up to the body and threatened his life. The lancet had repeatedly and freely to be used, and was followed by a copious discharge of pus for several weeks. During the whole treatment he said he experienced no pain. He said he felt no pain when his eyes were operated upon for cataract; neither did they inflame. I can vouch for his statue-like immobility during the second operation. When his neck was pustulated by tartar emetic ointment he did not feel it, but ordered the application to be repeated. I made three incisions with a bistoury in his neck to relieve erysipelatous inflammation. He was so unconscious of the operation that after it was performed he asked me to do it, that he might turn over on his back in the bed. He told his attending physician that he never suffered pain from any cause whatever until his last illness. For some days after its development he complained of the erysipelas, and then passed into his usual insensible condition before the state of coma supervened.

"It is proper to say that Mr. A—— was a man of great probity, and never boasted of being insensible to pain. The only cause suggested for this truly singular and peculiar condition of the system of this patient, is the free use of alcoholic potations, to which he was at one time much addicted. But others have drank more than ever he did without producing the same result. We think the case of sufficient interest to deserve a passing notice."

One would like to know how much inconvenience this man suffered from his peculiar lack of pain sense. I have in vain made effort to learn more of him. I use his case first to turn your attention to the curious speculation of man's capacity to learn the value of other modes of warning besides pain, and then as a text for my final remarks in regard to certain forms of pain.

I think if there be one thing more than another that we all dislike to treat, it is pain in the back. As a rule, in the study of cases of backache, one easily excludes certain things as causative. We know the so-called spinal irritation, the renal aches, the reflex from hæmorrhoids, the obvious offspring of ataxia, and the other distinctively featured neuralgias. Very frequently we are pulled up short, and, if intellectually honest, say to ourselves we do not know. A word is wanted for this negative decision. It is unpleasant to confess ignorance in blunt Saxon—we might easier say we had made an *Agnosis*. Accept my label, and let us go on.

Among these annoying cases are a certain number due to strain. You are familiar with the acute pain which comes when, a few little fibres having been torn of a sudden by the violent action of their fellows, a small hemorrhage follows, and then, perhaps, long-lasting mischief. But this is not what I mean. A man who is out of condition, gonty, rheumatic, or on the down-hill of life, makes a prolonged and unusual muscular effort, as in rowing or in restraining unruly horses; or it is a woman not well, or who at her menstrual times lifts a patient day after day, or stands too long. At times the subject who suffers is an athlete over-trained, or with muscles over-used. As a result of such conditions we have a pain in the back which, in a few hours or by degrees, reaches a maximum of annoyance. Is it a disorder of muscle or of nerve-centre? The pain in the back gets a variety of labels as doctor after doctor treats it and fails in his predictions of success. The intellectual vanities of most of us must pretty often have been crippled, for a brief hour at least, by these cases of pain in the back; but that cripple recovers easily. I confess myself to a prophetic sense of defeat when a man, especially a man, tells me that he has old chronic pain in the back. Very often it will prove to be one of these rather mysterious evolutions, the final offspring of excessive taxation of that neuro-muscular group which is, of all others, in most constant use; in fact, never out of use except when we are at rest supine.

The ache is, in these cases of strain, at the pelvic attachments, and runs down into the sacral and gluteal region; a permanent but variable ache, with slight and rare tenderness in this place or that, increased by exertion and troubled by an east wind. Sometimes it needs careful study of a life-history to bring out the true cause, or causes, for most disorders have several parents. As it is worse for much exertion, so, too, is it worse on waking in the morning, and long continuance in one position seems for a time to increase the ache and the attendant stiffness. Such pain, the result of what I venture to call chronic strain, whether muscular or nervous, may be slight, or enduring and disabling; indeed, may be incurable like some head strains, for you may strain nerve-cells as well as muscle-fibres. I use the word

[1] Southern Medical and Surgical Journal, 1849, vol. v.]

strain for lack of one more descriptive. These cases run here and there, wear jackets, plasters, are burnt, and what not. I said that some can no man cure. If the case be that of a woman, those pathological scapegoats, the womb and ovaries, get the credit, and with this new sin upon them are sent forth into the wilderness of surgical enterprise, leaving the diagnostic sinner relieved and released from further mental exertion. For some men, indeed, the ovaries are veritable treasure-houses on which they draw at will any amount of explanatory pathology.

You will pardon me if I say here that the causes of these distressful backaches escape detection, as a rule. Also if I urge that their early treatment by long rest and certain accessories gives the sole chance of permanent cure. Once this disorder is fully in possession, the incessancy of use of the parts concerned makes relief difficult. We treat these cases at the Infirmary by entire rest in bed for some weeks, by use of very hot water applied with hot wet mops to the back over a thick flannel. To use thrice a day, for half an hour, moist heat, as hot as can be borne, and not to blister is, let me assure you, not only most valuable, but needs a first-rate nurse. Then, once a day an hour's massage, mostly of the back, is added, and such general means as seem obviously needed. But let me say, too, the massage must be most searching, and the position of the back must be altered during its use so as to enable the rubber with thumb and finger-ends to reach and work at every part which can be gotten at. This triple means will cure some of these cases, and if used early, a good many; and then at last you may have to add, when the man gets up, if the case be an old one, some form of support or back splint.

The pathology of these cases is not very clear to me. But turn with me to a recent and very applicative research, and it may help us to comprehend this and certain other unsolved problems. All function must depend on ganglionic accumulation of appropriated and specialized material, which is expended and altered during activity. Says Dr. C. T. Hodge in a recent and valuable essay, "All admit coarse, visible changes as a result of normal use of glandular cells. It is my purpose," he adds, "to see how far this is true of nerve ganglion-cells. What difference is there between a cell long functionally stimulated and its fellows long at rest?" Dr. Hodge showed to the satisfaction of the American Physiological Society, two years ago, that after fatigue by excessive electric stimulation of the related nerves, the ganglion-cells undergo coarse changes. Thus these cells become smaller, the nucleus shrinks and grows jagged in outline, the surrounding protoplasm diminishes and loses materially its power to stain with osmic acid. Finally, numerous vacuoles appear in the spinal ganglion-cells, and in the brain-cells the shrinkage is still greater, and the pericellular lymph-spaces are more and more apparent.[1]

Once seen, these changes are such as easily enable one to say at a glance "This cell is tired; that cell is not." Dr. Hodge's first results were observed after electric stimulation, but now he has in press a paper I have read, in which he shows that such fatigue as arises from the flight of a bee or a bird, or the excessive tire of a chased fox, or the long journey of a homing pigeon, leave on the cells of spine and brain the most distinct signal-marks of exhausted protoplasm. Also excessive tire through muscle use is far more emphatic in its results than from electric stimulation. Even the nerve-fibres share in these results of work. The longer and the harder the work the plainer are these alterations, and the slower is the sequent repair. It takes twenty-four hours to repair five hours of electric stimulation. How easily one figures to oneself a state of too frequent and too severe work, repeated over and over before full repair is possible, as in time competent to carry the cells past the ready possibility of normal reparation.

See now what this means for us. You have at present only two words to describe the states of head or spine which follow excessive or difficult use of nerve, muscle, or mind. One man insists that the essential condition which should guide our therapeutics in these cases is cerebral anæmia; another, that it is cerebral congestion. There may be present the one or the other condition. Usually you do not know. Or, if there be too full or too empty vessels, are these not to be thought of as merely more or less mischievous accompaniments, or it may be, results. When we use imperfect eyes so as to fatigue to exhaustion the muscles of co-ordination or binocular relation, it seems probable that we must cause in their directing ganglionic cells states of tire with emphatic alterations. These by and by ring the signal-bell of pain, as worn-out tissues are apt to do soon or late. When Romberg wrote his much-used phrase, "Pain is the prayer of the nerves for healthy blood," he said a wise thing of limited value.

There are more things of which the nerves complain than of lack of normal diet; and one is the too perpetual demand on some imperfect part of the human machinery of which they make a part. The cry of pain seems to me, then, like the creak and squeal of disordered mechanism—more as if ill-used tissues had taken to profane language, than like any form of prayer.

In the case of the eyes, if ganglionic exhaustion has gone beyond normal ease of repair, we have increasing frequency of headaches and sometimes one form of that singular disorder, permanent headache. There may be congestion or not. The guiding therapeutic thought should, I think, be some conception of ganglionic masses wearied past the possibility of easy restoration. During war we used to see men so worn out by marching that the whole system of musculation and innervation became paretic. In these acute asthenic states the normal timetable of repair was disobeyed, and six months were needed to rebuild the ruined tissues.

It seems to me a vast gain to be able to add to our explanatory statements some demonstrable, reasonable explanation besides congestion or anæmia; also, it is of use to have ocular evidence of coarse change in connection with fatigue, and consequently with that readily-caused fatigue due to the effort to get normal vision with abnormal visual machinery. Then, too, Dr. Hodge's report encourages us to search anew and with confidence the neurasthenic organs in our rare post-mortem opportunities; assuredly we shall find obvious alterations; functional disease must always involve material tissue-change, just as does all normal function. If long continued, it must end at last by causing further functional incapacities due to more and more definite and lasting structural alterations—as normal function results in tissue changes which are, so to speak, the ruts of habit.

The more we become materialists in our views of so-called functional disease or disorder, the more likely are we to cure them. Take, for example, the various headaches of eye-strain. Once fully admit that long eye-strain involves tissue-change in the related ganglions, and we shall see that to glass correctly bad or imperfect eyes is not enough. And just here the oculist fails, if he is only an oculist. Certain headaches due to eye-strain continue despite his glasses. Then another man glasses the eye, and so on. What you really want is to correct the eyes, and to treat the over-wearied ganglia by putting the whole economy in the highest state of health. Then, indeed, and then only, are your glasses of much value; for there may be acquired states of a region, or of the whole body, in which the normal exercise of a healthy function is able to cause local or general distress; as when natural defecation gives rise to fainting, or healthy digestion troubles an excitable heart or an irritable brain.

I linger over this because I so often see the oculist or the general practitioner disappointed in the therapeutic influence of glasses, where obviously the eye is the starting-point in the product of headache. It is best on

[1] American Journal of Psychology, May, 1889.

the whole, in every such case, especially in the middle-aged, to explain that the glass rarely does its work suddenly, and that the habit of pain is apt to require added treatment which may be long and troublesome.

Headaches, as I think, furnish very interesting illustrations as to the causative relation of lowered states of health to pain. A man with bad compound hypermetropic astigmatism reaches middle age without knowing that he has bad eyes. A wife's illness, a business strain, or what not, taxes him sorely; thenceforth he has headaches, easily relieved by glasses. A woman has some defects of the ocular muscles. Her first nursing seems to set up headaches. They are called anæmic. She is treated until her blood-count is normal. There is no relief. Glasses cure her. At times women with bad eyes suffer only at the menstrual time from headache, which is not alone a womb reflex, and not alone eye-strain, but one of those abominable combinations of which we see so many. Glasses sometimes stop these headaches by removing one factor from the equation of mischief, which is then no longer equal to pain. Nor are these theoretical cases.

It had been my intention to discuss at length this matter of multiple causes in disease, and still using the cephalalgias to point out the frequency with which numerous conditions acting together at last evolve pain in the head.

I had meant also to deal anew with the cases in which a patient may have several forms of headache.[1]

But I have held you quite too long. As presiding officer of many meetings of medical men, I have been the more or less willing victim of those who talk at length of what their hearers know as well as they. Now and then I, myself, have a chance to test the patience of others, and this liberty I fear I have used with dreadful license to-night.

REPORT OF THE FOURTH LAPAROTOMY ON A HYSTERICAL PATIENT.[2]

By JOSEPH D. BRYANT, M.D.,
NEW YORK.

If the case to which I am to call your attention this evening were not one of unusual occurrence, and therefore of especial interest, I should be inclined to apologize to you for presuming to recite it; as such a course as this often appears to me not unlike begging the question when asked for a paper, and too, at the expense of the dignity and sincerity of the narrator as well as the patience and respect of the listeners. However this may be, the patient's name is N. N——, aged twenty-two, female, and an artist by profession. She was admitted to Bellevue Hospital, February 23, 1892. Her family history in no way bears on her medical history, and therefore will be passed. Her medical history, previous to admission, is somewhat striking, and in view of after developments concerning her, is quite suggestive of a unique personality.

1. She had had pneumonia twice, she said.

2 Also, typhoid fever and acute articular rheumatism three times, and diphtheria once.

3. She had had inflammation of the bowels three times, as she called it. The first attack of which lasted twenty one weeks, the second, six months, and the third, fifteen weeks. Each of these attacks began with pain in the left iliac region, was followed by chill, fever, and vomiting of blood, and attended with bloody stools. Each attack had led to a laparotomy. The first, according to her statement, was done by Kocher, of Halle, the second by one whose name she could not recall, in a town in the interior of Connecticut; the third, by Dr. Norris, of this city. About two months before admission to Bellevue, the pain began again in the same situation, was attended with a chill, fever, and vomiting of dark-colored blood, and the passage of bloody stools. Examination on admission disclosed general abdominal pain and tenderness, attended with fecal vomiting, bloody and mucous stools. Nutrient enemata were given, as she was unable to retain any food by the stomach. At this time it was suspected that she was suffering either from intestinal obstruction, or from a fistulous communication between the large intestine and stomach. Such was her history up to February 26th, at which time she was transferred to the surgical wards, and came under my notice. I examined her almost immediately after admission, and found her with a flat, boat-shaped abdomen, hyperæsthesia, with a normal temperature and a moderately increased heart-action. I was so certain that she had not intestinal obstruction, that I ventured the somewhat cannibalistic remark, "If she have intestinal obstruction, I will eat her." After giving some perfunctory directions to Dr. Wilson, the house surgeon, as to nourishment and the watching for further developments, she was left alone for a time. In the evening of the same date, Dr. Wilson visited my residence and reported that she had vomited a portion of a glycerine enema eighteen seconds after its administration. He also added that, being determined to be sure as to the identity of the vomited matter, that he had given a second enema, which one contained methyl violet, and that portions of this, too, were vomited in fifteen or twenty seconds after administration.

The identity of the coloring matter in this specimen of vomit was confirmed by no less an authority than Mr. Rice, the well-known chemist and pharmacist of Bellevue Hospital. As the expulsion by the mouth of portions of an enema so soon after administration, could not be accounted for rationally at that time except on the theory of the presence of a large fistulous communication between the sigmoid flexure and stomach, or the colon and stomach, directions were then given to prepare the patient for an operation to be done on the following day. It is proper to say now that the small size of the enema (three or four ounces), and the distance from the rectum to the stomach, taken in connection with the large size of the bowel conveying the fluid, did direct my attention to the fact of the strange inconsistency of its rapid expulsion by the mouth under these conditions. However, logic was not permitted to interfere long with action in this case, especially as the patient herself urgently requested an operation. On the following day the abdomen was opened in the median line, in the course of the incisions previously made by the other explorers, to which incision was added another passing through the left rectus at a right angle with preceding. The reason for the latter was to permit a better exposure of the stomach and transverse colon. On drawing aside the flaps the following conditions were easily determined: 1. General intestinal adhesions throughout the upper two-thirds of the abdominal cavity, so complete, in fact, as to practically obliterate the cavity in the immediate neighborhood of the operation. 2. The transverse colon in close contact with the greater curvature of the stomach, to which it was connected by old adhesions and shrunken omentum. Neither careful inspection nor manipulation disclosed the presence of a fistulous communication between the stomach and any portion of the intestinal tract, and the sigmoid flexure was found in the usual situation, and consequently far removed from the stomach. The tissues binding the stomach and transverse colon to each other were then carefully sundered, except the shrunken and distorted omentum, which was with difficulty turned upward at this situation, after division, between suitable ligatures. No evidences whatever of the presence of any intercommunication with the stomach rewarded this careful search, even after the stomach had been entirely separated from the contiguous intestinal surroundings. Still being anxious to interrogate the inner surface of the stomach, and also to examine as to the nature of its contents, a two-inch incision was made into it at the anterior surface, near the pyloric extremity. The introduction of

[1] International Clinics.

[2] Read before the Practitioners' Society, December 2, 1892.

the finger, the sponge, the douche, and the electric light disclosed nothing unnatural as to the physical characteristics or contents of the organ. The previous suspicions that had been entertained as to the possibility of counterfeit manifestations on the part of the patient were now promptly substituted by firm conviction of their spurious nature, and emphasized by wonder as how it all had been done. However, in order that all resources should be exhausted to detect the absence of integrity of the intestine, a large injection of a solution of pyoktanin was administered, with the transverse colon *in situ*. The colon was completely distended with the solution, beyond a doubt, since the characteristic color of the fluid could be easily discerned through the wall of the colon itself. During the introduction of this injection the left index-finger was placed in the pyloric valve, effectually closing it. This was done to demonstrate, in case of the fluid's appearance, whether or not it entered the stomach directly, or indirectly by way of the duodenum. But, as can now be foreseen by everyone, it did not enter at all. Consequently the incisions of the stomach and abdomen were closed in the usual manner, and the patient taken to the ward to await further developments.

She did perfectly well and nothing unusual appeared until March 12th, when a small amount of fluid fecal matter was noticed escaping through the ulcerating junction of the two abdominal incisions already mentioned. The fact was reserved for mention at this time, that, during the presence of the colored fluid in the transverse colon, the appearance of unusual thinness of the wall in an isolated part of the anterior border was commented on, and the fear expressed that it might slough there; therefore the wound in the abdominal wall opposite this point was closed only with an iodoform tamponade. From March 12th to April 28th the patient did well in all other respects than those referable to the fecal fistula; which now permitted the escape of nearly all of the intestinal dejecta. However, the patient improved in temperament and physical appearance during the time. On April 20th she again developed hysterical manifestations of no uncertain nature, such as great nervous excitement, attended with violent crying and complete ptosis. These symptoms continued with more or less interruption until May 9th, when she complained of great abdominal pain, continuous retching, attended with fecal vomiting. For the ensuing six days she was nourished entirely by the bowel. On the first of these days (May 10th) the vomited matter had the odor of whiskey, and possessed other characteristics strongly suggestive of the nature of the nutritious enemata that were being administered every four hours. On May 12th, at 5 P.M., her temperature was normal by the mouth, while by the rectum it was 113° F., as determined by Dr. Hubbard, the then house surgeon, after five trials with as many different thermometers, which were pronounced correct by Mr. Rice. On the following day (May 13th) the rectal temperature was 108° F., by a standard Hicks thermometer, while the axillary temperature was normal. On the same day the sphincter ani was dilated and a thermometer carried high into the bowel, with the result of registering 99°. From this time on the temperature was normal in all respects. During the six days of rectal alimentation, continuous fecal vomiting, and the occasional high temperature by the rectum, the patient's general condition, pulse, and the temperature elsewhere than in the bowel was normal, and for this reason it was believed that food was obtained in some surreptitious manner by the patient. As she still continued the vomiting of matters resembling the enemata, an enema of eosin solution flavored with the oil of cloves was given by the then house surgeon, Dr. Hubbard, and fourteen minutes later she expelled by the mouth an ounce of the mixture. Still it was fifteen hours after the giving of this enema before any evidence of it appeared at the fistulous opening in the abdomen. On the following day she was stripped while in bed and removed to the corner of a neighboring ward, there placed in another bed, her hands tied, and a continuous watch placed over her. She was then given as before a solution of methyl blue flavored with oil of cloves. She rebelled vigorously against the confinement as well as the scrutiny then being exercised. Finally she quieted down, and so also did all of her distressing symptoms. No more fecal vomiting occurred, notwithstanding her efforts of retching, which were soon discontinued. However, the enemata were continued as before, with the view of ascertaining if she would complain of hunger now while under their use, as she had not done so before this time. She soon begged for food, which was given her, and the enemata were discontinued. From this time on she made a continuous and prompt recovery, and was soon walking around the ward in fair vigor and good spirit. I requested Dr. Hubbard to exercise his own judgment as to the best manner of finding out how she had so completely deceived the attendants in the final, and presumptively on all previous occasions. After great effort she finally made statements regarding the deceptions which can be summarized as follows:

1. She knew that she was doing wrong, but the impulse to do so was irresistible.

2. That in the first instance (the glycerine enema), she fooled the nurse by removing some of the enema from the rectum with the fingers and placing it in the mouth, then, while being observed, retched and expelled it from the mouth with apparently great effort and suffering.

3. She obtained the methyl-violet while it was in a dish placed on the stand by her bedside, when the nurse was stooping down to place a vessel on the floor. Therefore she had it in her mouth ready for exhibition before the injection was given.

4. During the six days of continuous fecal vomiting, and the phenomenal high temperatures and rectal alimentation (all of which caused no well-marked physical change), she was well fed with milk by a patient of the ward during the absence of the nurse. The fecal supply of the vomit was taken from the abdominal fistula, put in the mouth by herself, and kept there to be expelled while under observation.

5. Portions of the clove-scented eosin solutions used as an enema were removed from the rectum by the patient with her index finger, put in the mouth, and expelled when necessary for the purpose of deception.

6. She refused to account for the high registration of the thermometer, saying "I do not know." But since the temperature of the rectum remained at the normal figure after dilatation of the sphincter ani, the means employed by the patient to cause this exaggerated registration would seem to depend in some manner on friction, incident, perhaps, to alternating rapid contraction and relaxation of the sphincter ani; for surely the sudden change after dilatation cannot be classed as a coincidence. So much referable to the remarkable knowledge and shrewdness displayed by the patient in carrying on the deception. There can be but little doubt of the fact that those who were previously in charge of this patient were led to perform laparotomy upon her because of the presence of simulated obstruction or other phenomena which she then exhibited. Her anxiety to submit to operation in the fourth instance, with the full knowledge of its dangers and failure in her case, and the appreciation that her own impulses were causing the deceptions indicating its performance, lead me to classify her as a "laparotomy fiend" of the highest order.

I will occupy only a few moments more while I call the attention of my surgical friends to some features of surgical interest in this case. A few weeks ago an effort was made by me to close the fistulous opening in the abdominal wall. It was then about one-fourth of an inch in diameter, and led directly into the transverse colon, for the walls of this intestine were adherent to the posterior surface of the abdominal wall. The gut was dissected away from the abdominal wall, the border of the opening in it refreshed, and then closed in the

usual manner. As the result of this procedure, and other influences, the lumen of the intestine was reduced perhaps about one fourth at the seat of sewing. The effort to close it was a failure, due in part, and perhaps entirely, to the fact that the patient inserted her hands beneath the dressing and into the wound soon after the operation, and they were tied to prevent further similar acts. At all events, there still remains an opening, through which a quite free discharge of fecal matter takes place. In conclusion, permit me to submit the following interrogatories :

1. Is a diminution of one-third in the lumen at the seat of closure sufficient to offer a serious obstacle to healing at that point, or to interfere after healing with the proper performance of the intestinal functions ?

2. Will the adhesion to the abdominal wall of not less than four inches of the anterior surface of the colon at the point of closure, either alone or combined with the general intestinal adhesions noted in this case, offer an obstacle well calculated to prevent permanent cure of the fecal fistula, without excision of the adherent portion of the transverse colon ?

3. Was or was not the fecal fistula caused by sloughing of the wall of the colon, itself dependent on an incautious or unavoidable stripping off of the peritoneum at that situation ?

Dr. Bryant also read the following case in the practice of Dr. J. M. Leslie, of Chillicothe, O. :

"In the first year of my practice (1876), S. B—— was sent to me for treatment by Dr. E. J. Galbraith. She was about twenty five years old, unmarried, of German parentage, and American birth. She had light hair, blue eyes, and a sallow complexion ; was illiterate, unsightly, and poor. An abscess of the dorsum of the right hand opened between the metacarpo-phalangeal jomts of the middle- and ring-fingers. After several months of—the then—ordinary treatment, without improvement and without remuneration, I advised her to try someone else, telling her I would have nothing more to do with the case unless the dead bone showed itself, in which case I would remove it for her. (I had suspected dead bone at the bottom of her trouble.) About a week later she came in and told me that she thought that there was a piece of dead bone in her hand. I probed, found, and removed it with dressing-forceps. The next week she came in with another piece of bone to be removed, and the following week with two pieces, and the week after that with three, and so on, the number of pieces increasing from week to week until I removed eleven, the highest number removed at any one sitting.

"Probably the first fifty were thrown away as fast as removed ; those removed later were dropped in a box and saved. The box is now in my possession and contains three hundred fragments of bone, all of which were taken from this same hand. They measure from seven-eighths of an inch to two inches in length, and from one-eighth to one quarter of an inch in width, and were evidently split from the bones of chicken legs which had been boiled. The majority of them are rough, but a few have been whittled down and sharpened at one end to facilitate introduction.

"The bones were always wedged in tightly and the opening partly, sometimes completely, closed over them. To remove them it was necessary to enlarge the opening with a knife, locate the bones with a probe, grasp one of them with a forceps, and make a good, strong pull ; they came away with a grating sound, and were followed by a stream of blood and pus. The bones were always pushed deep into the hand, and well up toward the wrist, and when I cut down on them making a new opening, she pushed them still farther up, or to one side.

"The hand was always very much swollen and distorted, and must have been very painful, yet she was never more delighted than when she had a goodly number of bones to be removed.

"Tiring of her, I finally refused to have anything more to do with the case. I saw her a year or two later, when she told me that about twenty-five bones worked out after I quit the case, and then her hand got well. She always denied putting them in.

"This same patient had previously a number of sound teeth extracted, for no other apparent cause than the pleasure of extraction. She also took pleasure in having epileptic fits on the public highway."

NOTE ON THE USE OF HEART-STIMULANTS, AND PARTICULARLY OF STRYCHNINE, IN THE TREATMENT OF ACUTE LOBAR PNEUMONIA.[1]

By J. WEST ROOSEVELT, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL ; CLINICAL LECTURER ON MEDICINE IN THE COLLEGE OF PHYSICIANS AND SURGEONS ; ATTENDING PHYSICIAN TO THE ROOSEVELT HOSPITAL ; VISITING PHYSICIAN TO BELLEVUE HOSPITAL.

NEW YORK.

THAT death in a large number of cases of acute lobar pneumonia is directly caused by the exhaustion of the heart which the disease-process produces is generally admitted. It is well known that patients suffering from this malady are very prone to syncope upon slight exertion ; indeed, a number of cases are on record in which sudden death has followed the effort to sit up in bed for the purpose of facilitating the physical examination of the chest. In a considerable number of cases death takes place very suddenly, as it sometimes does in pleurisy with effusion, from syncope not caused by muscular exertion. In still others œdema of the lungs precedes the fatal issue. In all these cases it is the heart-failure which kills. With the causes of this failure we have but little to do in the present paper. It is my desire to speak only of certain clinical phenomena, not to discuss theories

Acute lobar pneumonia is a self-limited disease, which usually terminates by crisis within ten days. In very many cases, sooner or later the heart becomes weak, and in fatal cases death often results from heart-failure. Sometimes the heart-weakness is manifest at the beginning of the disorder, but more often it only becomes evident after the illness has lasted several days. It is very apt to be pronounced about the time the crisis is generally to be expected, and death is very common at this time (*i.e.*, between the sixth and tenth days). The disease is of short duration ; if the heart can be forced to act for a few days recovery may be expected, and there is reason to believe that judicious treatment with cardiac stimulants can save many lives.

The principal stimulants commonly used in pneumonia are alcohol in some form, digitalis, convallaria, and strophanthus, either singly or in combination, caffeine, ammonium carbonate, ether, some of the nitrites, opium, musk, nux vomica.[2] There are, of course, a number of other heart-stimulants ; but the ones mentioned are the most important.

The Indications for Stimulation.—There is, it seems to me, a good deal of difference of opinion as to the indications for exhibiting stimulants. On the whole, are we not apt to use them before the patient's condition demands them ? The principal reason for their administration is their effect upon the circulatory system ; their action upon the rest of the body-machinery is not taken into account. (It will be understood that I speak of the drugs named only as they are employed for the purpose of "stimulation" in the clinical meaning of the word.) There is an idea which has been often set forth, and which is often applied to-day, that it is right to stimulate in all cases where there is reason to expect weakness of the heart to result from some acute disease long before such weakness becomes manifest. Syllogistically expressed in regard to pneumonia, it is : "Heart-weakness

[1] Read at a meeting of the Practitioners' Society, December 2, 1892.

[2] The alkaloids of the various vegetable substances are assumed to be included under the name of the plant producing them

may be expected to result from the disease within from twenty-four hours to ten days; therefore, let us forestall it by immediately giving stimulants, regardless of the present condition of the heart." This is the actual practice of many. It would be as rational to say to an athlete, "You are to be submitted to a severe strain in a short time; you had better take a good deal of liquor." The athlete knows that to take stimulants in order to prepare for some strain upon his muscles which is not imminent, is folly. The heart is a muscle, and to stimulate it needlessly is to exhaust it. The need for stimulation is determined by the actually existing condition of the circulatory system, not by some condition which may obtain in the future. If a patient with pneumonia has a good pulse and shows no evidence of imperfect circulation, it is worse than folly to stimulate.

Concerning Some of the Cardiac Stimulants.—Alcohol administered in wine, liquor, or some other solution, is of the greatest value. It is needless to say more about it than has already been said, namely, that it is not well to give it without definite reason. In regard to digitalis, strophanthus, and convallaria, I can only say that I have never seen a single case of pneumonia in which benefit seemed to result from their use. This may be because of my limited experience, but it is a fact. Opium and morphine have both seemed to be of distinct value as stimulants in a number of my cases. Passing over the other drugs, I wish to call attention to strychnine as a cardiac stimulant.

Strychnine has been in use for this purpose for a long time. I have not been able to learn who first recommended it. Its value does not seem to have been appreciated by the majority of the profession. While I do not pretend that it is capable of producing marvellous effects, I think it has a value which should not be overlooked. Especially is this so in patients in whom alcohol is powerless, as in old drunkards. It has seemed to me to increase the heart's strength in a remarkable way in a number of such cases. It has also seemed a most valuable drug when given in addition to alcohol in suitable cases, since it appears to increase the stimulating effects of the latter.

Administration and Dose of Strychnine.—It must be given in large doses. By far the safest mode of administration is hypodermic. Given in this way each dose exerts its influence promptly, and there is no tendency to cause the so-called "cumulative action." From $\frac{1}{30}$ to $\frac{1}{20}$ grain may be given at a time, and the same or a smaller dose repeated every half-hour, if necessary, until the heart becomes stronger or toxic symptoms begin to appear. The limit of safety may be assumed to have been reached as soon as a distinct exaggeration of the deep reflexes appears. The way I have adopted for demonstrating such an exaggeration is very simple. It is to lift the patient's forearm, the hand being allowed to hang with the extensors relaxed, and to strike the tendon of the supinator longus. If a marked contraction of this muscle occur, it is fair to assume that the reflexes are exaggerated.

Strychnine is what might be called an honest drug, for it gives warning of toxic symptoms long before the latter appear, provided it is used hypodermically. I repeat that I do not wish to claim for it more than a limited range of utility, though I think it may prove as valuable as alcohol for heart stimulation.

The Hospitals of New York City have received quite a shock in the last month, from the order of the Fire Commissioners in regard to a new law, which seems to have been passed when the Legislature was in a state of panic. This law compels even small hospitals to have night watchmen, and, besides that, a very complicated annunciator and gong apparatus, which is likely to be set in motion by some timid patient and wake up the whole house, without any good whatever.—*Post-Graduate.*

THE USE OF ELECTRICITY IN MIDWIFERY.[1]

By OGDEN C. LUDLOW, M.D.,

NEW YORK.

MR. PRESIDENT AND FELLOWS: It requires no very great stretch of imagination to fancy the more conservative among you saying to themselves, as they glance at the title of this paper—"I suppose some young enthusiast is going to try and make us believe that electricity is capable of doing almost anything in midwifery, and that our time-honored drugs and instruments must be thrown aside, and our obstetric outfit reduced to a battery and a few electrodes." If there be any such here to-day, let me relieve their mind at once, by stating that it has been the aim of the author to avoid the rosy-hued descriptions so often indulged in by writers upon the medical uses of electricity, and to confine his paper to a concise and scientific statement of some points which his own experience has led him to think may be of practical interest to his fellow-practitioners.

There are many occasions on which the resources of the obstetrician are taxed to the utmost, and our science has not yet become so exact that we can say with certainty that this or that remedy will be the appropriate one for a given case. Even the physician of large experience, who has learned to make the most of what is at hand, cannot afford to ignore any measure, however trivial, which has been found helpful in practice; and it is hoped, therefore, that the value of electricity in midwifery will be judged, not by theory, but by the actual test of experience. It is not an agent which will suit every case, or which can be applied according to mathematical rules; like other therapeutic measures, it frequently fails, but nevertheless, it possesses certain important advantages, which, in the opinion of the writer, entitle it to a permanent place in the recognized resources of obstetric art. Whenever the generic term "electricity" is employed in this article it is to be understood that it refers to faradization, as this form of electricity is by far the most useful, as well as the most convenient, for our purpose.

For convenience in description, its more important uses may be considered under three heads, viz.: I. Its sedative action. II. Its oxytocic action. III. Its power to prevent, and to control, uterine hemorrhage. To avoid needless repetition, these three principal actions of electricity will be considered first; then a few cases will be cited, which have been selected for the purpose of showing where electricity has been of service, and where it has failed; and finally, the method of its application will be considered,

I. Its Sedative Action.—Happily, public opinion no longer considers it improper to attempt to relieve the sufferings of the parturient woman, and those physicians who still persist in withholding remedies which are known to mitigate the pangs of child-birth, do so, not because they believe that woman is doomed "in sorrow to bring forth children," but from a deep conviction that the administration of such drugs is not for the best good of their patients. At our last meeting, I took occasion to express myself as heartily in favor of the judicious administration of chloroform in most cases of labor, but I recognize that chloroform has some disadvantages, and I am sure that all of us would gladly welcome any agent which, while exerting a marked sedative effect, would not interfere with the progress of labor, or tend to produce post-partum hemorrhage. Such an agent is to be found in the faradic current of electricity, but you will be disappointed if you expect it to exhibit this action in every case. I regret very much that my own experience with faradization does not permit me to endorse the claims made for it by Dr. W. T. Baird, of Texas. In an article written by him, and published in the *American Journal of Obstetrics* in 1885, he says that the suffering can be as ef-

[1] Read before the New York State Medical Association, November 17, 1892.

fectively relieved in the painful parts "as we would dare to relieve it with anæsthetics, *for any great length of time*," and adds that he has never known of a case in which it has failed to give all the relief demanded by the patient. This is pretty strong language, and is only applicable to some of the more striking cases which have come under my observation. In his experience with electricity in midwifery the writer has met with the same uncertainties and disappointments which characterize the action of other remedies, and he has thus far been unable to formulate rules which would be of much assistance in determining which cases are most appropriate for its use. In saying this, however, he does not wish to be understood as implying that it is more difficult of application than such remedies as chloroform, morphine, and chloral, but only that in this field, as elsewhere in medicine, empiricism must play an important part.

But, you ask, what are the special advantages; then, of electricity over other remedies? In the first place, it is useful where chloral or morphine is contra-indicated on account of idiosyncrasy or debility, or where it is not considered prudent to push these drugs any further. It is also available where the stomach is too irritable to retain medicine, and where it is inconvenient or impracticable to resort to rectal administration. Faradization, unlike morphine or chloroform, does not interfere with the progress of labor by stopping "the pains," but, on the contrary, excites more powerful and efficient uterine contractions, at the same time that it quiets the general nervous irritability. It also possesses the distinct advantage of not favoring uterine relaxation and hemorrhage, and its use, therefore, does not complicate subsequent operative procedures under anæsthesia, should these be demanded.

The manner in which the faradic current produces sedation has long been a fruitful subject for speculation, yet up to the present time but little is definitely known about it. The older writers compared its action on the nerves to that of counter-irritants upon disease processes; or, in other words, they claimed that by producing a profound impression upon the nerves of sensation it prevented them, for the time being, from transmitting the sensation of pain. More recently we have been told that it probably causes anæsthesia by producing a sort of rapid inward percussion upon the nerves. That the number of vibrations of the current has much to do with its anæsthetic effect, has been admirably shown in a recent paper, read by Dr. William F. Hutchinson, of Providence, before the American Electro-therapeutic Association. He has had constructed an induction apparatus, in which the usual spring vibrator has been replaced by a metallic ribbon, which may be readily adjusted to vibrate in unison with any desired note, and his experiments upon the human subject with the current from this apparatus, have brought out the remarkable fact, that when this ribbon sounds the note of C major, or is vibrating about thirty thousand times per minute, the maximum anæsthetic effect is obtained. So marked was the anæsthesia that he was enabled, in one instance, to open a felon without causing the patient any pain whatever. I mention these experiments, not only because they throw some light on the action of the faradic current upon the sensory nerves, but because they show plainly that we cannot expect to obtain this exceedingly useful effect of the current from every little induction apparatus which we may happen to employ.

II. **Its Oxytocic Action.**—If there be one action of electricity more certain than another, it is its power to evoke and stimulate uterine contractions; hence, in every case of tedious labor in which the delay is due to feeble or infrequent contractions of the uterus, or where, owing to slight disproportion between the fœtal and maternal parts, unusual muscular exertion is required to deliver the child, faradization is indicated, and will usually render efficient aid. Not infrequently the exhibition of its sedative action is immediately followed by a distinct advance, thus showing that in practice its sedative and oxytocic actions cannot always be separated. In persons of sensitive temperamenta slight benumbing effect, whether produced by drugs or by faradization, is sufficient to encourage the patient to "bear down" more vigorously, and so make better use of the "pains" of the second stage. One of the most beneficent properties of electricity is exhibited in what may be termed its "steadying effect" on "the pains," by which is meant that the uterine contractions, when severe and almost incessant, are made less frequent and more efficient. It is just here that one appreciates the importance of that rest which is afforded the uterus, when the contractions are of the regular, rhythmical type seen in a perfectly normal labor.

Notwithstanding all that has been written and said against the danger of administering ergot to hasten labor, there are not a few practitioners who persist in this practice. To these physicians, as well as to those who are often sorely tempted to use it in this way, but who have moral courage enough to refrain, I would recommend a trial of faradization. The action of ergot is slow, and uncertain in degree, faradization produces its effect instantaneously, and the amount can be accurately gauged; ergot exerts its influence for a variable length of time, which is entirely beyond control, faradization acts upon the uterus for just so long a period as the operator desires—it can be instantly checked, and as quickly resumed; ergot produces a tonic cramp of the uterine muscle, which unnecessarily exhausts the mother, and is dangerous both to her and to the child, faradization produces a steady, rhythmical contraction of the uterus, which allows a proper interval of rest to the uterine muscle, and closely imitates Nature's method. In no class of obstetric cases does electricity possess such signal advantages over other and better known measures as in that in which a safe, speedy, and certain oxytocic agent is indicated. I say "indicated," because there are many cases, besides those due to simple inertia of the uterus, in which such an agent is desirable. Thus there is often a slight narrowing of the pelvis, or the fœtal head is unusually large, or is abnormally ossified, causing a tedious labor, and yet, at the commencement, it is impossible to say whether or not delivery can be safely effected without instrumental aid. Under such circumstances, it is true conservatism to make an effort to accomplish delivery without resorting to instruments, or to an operation, and this is especially so, when that effort does not involve any additional risk. No evidence has yet been brought forward to show that electricity, as ordinarily applied, is harmful, either to mother or child, so that one has nothing to lose, and everything to gain, from a trial of its oxytocic properties.

Faradization is likely to prove very useful in those occasional cases in which the induction of labor becomes imperative. On account of the comparative rarity of this procedure, only one such case has come under my personal observation, in which this agent was so employed; but in this instance, its action was so admirable, as to place it far in advance of the methods usually recommended. In cases of inevitable abortion and miscarriage it is also an extremely valuable agent; but this will be again referred to in considering its action in the third stage of labor.

III. **Its Power to Prevent, and to Control Uterine Hemorrhage.**—Under this head will be considered more particularly its usefulness in the third stage of labor. As in all cases where uterine inertia already exists, or is likely to be present, there is danger of hemorrhage in the third stage, the indication is to employ such treatment as will place the uterus in the best possible condition to prevent such a mishap. The usual practice is to do little more, in the way of prophylaxis, than to guard against undue exhaustion of the patient, and to avoid emptying the uterus too rapidly. The best authorities advise against the use of ergot until it is certain that the second stage of labor will be completed within a very few minutes, and

many prefer waiting until the child is delivered before administering this remedy. The writer prefers the latter plan, and is of the opinion that the giving of ergot a short time before delivery is often responsible for difficulty in removing the placenta. This objection does not apply to the use of electricity, for, as has been already stated, the contractions of the uterus which it produces, are entirely under the control of the operator. Among the more common causes predisposing to post-partum hemorrhage may be mentioned rapid emptying of the uterus, and the use of chloroform to the point of producing profound anæsthesia. Where there is imperfect contraction of the uterus after the delivery of the placenta, or where post-partum hemorrhage is imminent, or is actually present, faradization is very useful, and when the hemorrhage is not excessive, may be all that is required. I do not wish to be understood as advocating its use in the face of an alarming hemorrhage, to the exclusion of well recognized methods of treatment, for this might mean the loss of valuable time and, perhaps, even of a life; but, if the electrical apparatus be in readiness beforehand, as it should be, it will be found a valuable adjuvant to other methods, just as a hypodermic injection of ergot may give temporary aid, after the obstetrician has removed any portions which may have been retained in the uterus, and when, perhaps, a few precious moments would otherwise be lost while hot water for a douche was being brought to the bedside, or its temperature was being adjusted.

Electricity is also useful in aiding the expulsion of the placenta. Most obstetricians will be able to recall cases in which, owing probably to fat abdominal walls, or still more commonly to distention of the bowels with gas, the placenta has been delivered only after considerable manipulation, which has left the abdomen sore and tender. By calling electricity to our aid we shall be able, in most cases, to expel the placenta with scarcely any manipulation of the abdomen, and with a trifling loss of blood.

Analogous to the assistance rendered by electricity in the third stage of labor, is its action in cases of abortion. Here it may be resorted to with good effect, saving much time and annoyance, both to patient and physician, by doing away with the necessity for prolonged manipulations, and so diminishing both the dangers and the discomforts attendant upon such accidents. For instance, in those cases of early abortion occurring in women in whom the cervix is high and the ostium vaginæ quite small, it need hardly be said that the removal of the contents of the uterus is often attended with much difficulty; yet it is just under such conditions that faradization does yeoman service, for it not only causes the expulsion of the contents of the uterus, but also guards against one of the most common complications, *i.e.*, hemorrhage.

From what has already been said, one would very naturally and properly infer that electricity would be useful in cases of subinvolution, and while this is true the limits of this paper prevent a consideration of this and such kindred subjects, as the use of faradization to stimulate the secretion of milk, or for the relief of the vomiting of pregnancy.

It has been the object of the writer, thus far, to give a general idea of what may be expected from faradic electricity in obstetrical practice. It remains now to consider briefly a few illustrative cases, and then take up some practical points regarding the technique of its application.

As some of the following cases were observed in hospital practice jointly by Dr. Irwin H. Hance and myself I am indebted to him for some of the clinical notes.

Case I. *A Good Sedative and Oxytocic; Prompt Control of Post partum Hemorrhage after Forceps Delivery.*—I-para; twenty-eight years of age. The first stage lasted twenty-one hours, and the pains were fifteen or twenty minutes apart. At the beginning of the second stage faradization was begun, and was kept up almost continuously for forty minutes. The pains were then more vigorous, and came on about every five minutes, yet the electricity produced a marked sedative effect, which was commented upon both by the patient and the nurse, although I had been careful to refrain from saying anything about the severity of the pain. The current was then applied for some little time longer, but only during the pains, which became somewhat less frequent again, but still quite strong. The head was obstructed at the pelvic floor, and after waiting a considerable time, the forceps were applied under full chloroform narcosis, and delivery effected in twenty five minutes. The tonic contraction of the uterus was not very good after the delivery of the placenta, and there was a small gush of blood, which was instantaneously checked by the application of the electrode.

Case II. *A Good Sedative and Oxytocic.*—II-para; twenty-two years of age. The first stage was characterized by almost constant nagging pains, and after some hours, although the patient was quite plucky, she became very nervous, and her pulse rose to 120 beats per minute. At the time of beginning the faradization the os was about two and a half inches in diameter, thick, and unyielding, and the head of the child was quite high in the pelvis. In from three to five minutes, it was evident that the patient was suffering much less, although the uterine contractions were frequent, short, and sharp. In a few minutes more the os was fully dilated, and the head on the perineum, and the child was delivered in half an hour. The electricity was applied at intervals during this period until just before the delivery of the head. The patient had become quite calm, her pulse had been reduced to 104, and was of better quality, and the uterine contractions were much more regular and effective.

Case III. *A Good Sedative and Oxytocic; Useful in the Third Stage; Effect of Varying the Interruptions in the Current.*—I-para; twenty five years of age; a large and strongly built woman. The dilatation of the os was very slow, so that thirty-six hours after the first pains began it was only about two inches in diameter. Seven hours later, notwithstanding the use of several hot vaginal douches, and the evacuation of considerable liquor amnii, the os was not much larger, and the pains were irregular, short, and inefficient. The full strength of the current from a large faradic battery was then applied in the usual way, and after about fifteen minutes of almost continuous application, the pains had become more regular and frequent, and had increased in severity, yet the patient was much quieter, and expressed herself as experiencing much less pain. The application of the current lasted for half an hour. After this, the progress was more decided, and the os was fully dilated in a little less than four hours. There was slight obstruction to the descent of the head in the pelvis, so the forceps were applied, and the head soon delivered by gentle intermittent traction. There was some little difficulty in delivering the placenta, and its expulsion was followed by more than the usual amount of bleeding, and although this was checked by ergot and hot douches, the uterus remained flabby. The faradic current was again applied for about five minutes, with the result of causing a firmer contraction of the uterus and preventing further hemorrhage.

In this case it was found that the most work could be obtained from the current with the least inconvenience to the patient, by adjusting the contact-breaker so as to make very fine interruptions in the current during the intervals of the pains, and changing to coarse interruptions as soon as the uterus began to contract.

Case IV. *Prolonged First Stage from Rigid Os; Faradization Fails Both as an Oxytocic and a Sedative; Chloral Succeeds.*—I-para; twenty-one years of age. She had pains at short intervals for four days before any dilatation of the os was evident. When the os had reached two inches in diameter there was scarcely any further progress. The uterine contractions occurred every three minutes, and were very strong, but with each pain the os would dilate to nearly the full size, and then contract to

its former size when the pain subsided. During the night the patient received three hot vaginal douches and thirty grains of chloral, but with little benefit. A strong faradic current was then applied, almost continuously for fifteen minutes, and then only during the pains for fifteen minutes more. The uterine contractions then became very severe, and recurred every two minutes, but there was no advance and no sedation, and the faradization seemed to cause so much discomfort that it was stopped. During the next four hours the patient received three hot vaginal douches, and thirty grains more of chloral. She then came pretty well under the influence of the drug, and at the same time it was noted that the child's head was lower, and that the cervix was receding. The progress of the labor from this point was uninterrupted, and the child was born two hours later.

This case is worthy of special notice, not only because of the failure of electricity to accomplish good results under conditions which seemed theoretically to be peculiarly appropriate for its use, but because it also shows that the writer does not wish to convey the impression that electricity will accomplish wonders in every case. Contrast this case with the following:

Case V. *Good Oxytocic Action and some Sedation; Chloral Fails.*—I-para, twenty-eight years of age. The first stage was quite slow, the os being only about one inch in diameter at the end of twenty two hours. The cervix was thin for a long time before the os dilated, and the head was low down in the pelvis, but the pains were not very strong. Chloral failed to assist the dilatation. The faradic current was applied continuously for twenty minutes, and produced some sedation. The second stage began fifteen minutes later, and was completed in half an hour.

Case VI. *Marked Sedation, although no Effect upon the Os; Pelvic Contraction; Forceps Delivery.*—I-para, twenty-five years of age. After being in the first stage for twenty-four hours, suffering severely, it was found that the os was only about two inches in diameter, and its margins quite thick. There were severe uterine contractions every five minutes, and hot douches and morphine had given no relief. Faradization was employed continuously for thirty minutes, with the effect of producing more efficient uterine contractions at longer intervals, and causing the entire disappearance of the nagging pains in the back and hypogastric region. After the second stage was reached it became evident that the mother would require assistance, so the forceps were applied, and delivery effected.

This case is presented in order to show that even in the presence of pelvic deformity, relief from pain may be obtained by the use of electricity, when morphine in appropriate doses has failed. In view of the fact that, in such cases, it is probable that an operation under an anæsthetic will ultimately be required, it is obvious that it is safer to apply electricity than to administer chloral or chloroform.

Case VII. *Induction of Labor in Fifteen Minutes, by Faradization.*—This patient, a primipara, thirty-one years of age, with a decidedly phthisical family history, had suffered, for a long time previous to her pregnancy, from gastritis, and had been further debilitated during pregnancy by persistent nausea and vomiting. After her admission to the hospital she rejected all stimulants and food, with the exception of a little milk and carbonic acid water. In view of her wretched and somewhat precarious condition, it was decided, after consultation, that as the computed time of her confinement had arrived, it was not advisable to wait any longer, and that labor should be at once induced. On the day she had expected to be sick there were no uterine contractions, and no indications of the onset of labor; the os only just admitted the tip of the finger, the vertex presented in the L. O. A. position, and the fœtal heart was beating strongly. The ptient was very weak and excessively nervous and apprehensive. The electrodes were applied in the usual manner over the sacrum and abdomen, and the strength of the faradic current adjusted so as to be slightly disagreeable, but not painful. While the current was being applied Dr. Hance attempted digital divulsion of the os. The first uterine contraction occurred four minutes after applying the current, and several others followed in rapid succession. At the end of twelve minutes from the beginning of the application the os had dilated sufficiently to admit two fingers. Faradization was then stopped for a few minutes. In twenty five minutes from the beginning of the séance the os admitted three fingers, and was quite dilatable, and the pains were returning regularly at intervals of three or four minutes. In the next twenty-five minutes the current was applied only during the uterine contractions. The pains were now only two minutes apart, the mother was much more composed, and her pulse was 68, regular, and fairly good. Labor being now well established faradization was discontinued. The first stage lasted four hours and the second only thirty minutes.

Case VIII. *Expulsion of the Placenta by Electricity; Less than the Usual Bleeding.*—I-para, twenty-one years of age. The faradic current was applied only during the pains near the termination of the second stage, and was then omitted for about five minutes, until the umbilical cord had been ligated. On again closing the circuit the uterus promptly contracted, and in a moment the placenta was forced into the vagina. Although chloroform had been administered sparingly during the last few expulsive pains, the delivery was attended with practically no hemorrhage. About three years later I attended the same lady in confinement with her second child. The first and second stages together only occupied a little over two hours, chloroform was given in the same way during the last fifteen minutes of the second stage, and faradization was not employed at all. There was considerable more blood lost than at her first confinement, when the electricity was used, but the amount still did not exceed that found in many normal deliveries.

Case IX. *Hour-glass Contraction; Adherent Placenta; Faradization Fails.*—III-para, thirty-three years of age. After applying the current for a reasonable time, it was found that the expulsion of the placenta was hindered by a contracted ring in the lower segment of the uterus, and also by the placenta itself being adherent. An examination of the placenta after delivery showed its cotyledons to be unusually large and soft. No ergot had been administered.

Case X. *Placenta Expelled; Immediate Arrest of a Slight Post-partum Hemorrhage.*—I-para, twenty-five years of age. An application of the faradic current in the usual way caused the prompt expulsion of the placenta from the uterus into the vagina, and then very gentle downward pressure with the electrode, resulted in the placenta being immediately forced outside of the vulva. Just after stopping the current there were a few gushes of blood from the uterus, but this hemorrhage ceased immediately on closing the circuit again, and after a few minutes the uterus remained firmly contracted without artificial aid.

The foregoing cases are representative ones, and have been selected with the object of showing what electricity can do, and what it cannot do, in the practice of midwifery. Looking over those cases of which I have preserved careful notes, and in which electricity has been employed with a specific object in view, I find that in 12 cases in which faradization was employed for its sedative and oxytocic effects its sedative action was shown in 8 and its oxytocic action in 9 cases. In 20 out of 27 cases in which it was employed in the third stage of labor it materially aided the expulsion of the placenta, and in 3 out of 4 cases of *moderate* bleeding, occurring immediately after delivery, it promptly checked the flow, and produced firm uterine contraction.

No doubt, by this time, some of you have been thinking that this employment of electricity in midwifery is

pretty in theory, and perhaps useful in hospital practice, or where there are more facilities for using electrical apparatus than ordinarily fall to the lot of the general practitioner, but that it is of very doubtful application to the everyday routine of practice. I hope to show that such is not the case, and that the effects described in this paper may be obtained without the use of any elaborate, expensive, or cumbersome apparatus. I find no objection to the treatment on the part of the patients or their friends; on the contrary, they are gratified at the effort the physician makes to relieve the suffering, and are not slow to compare this practice with the more common one of sitting at the bedside and turning a deaf ear to the patient's pleadings. Do not misunderstand me on this point. I am no advocate of "meddlesome midwifery," but I do believe that the accoucheur should stand ever ready to assuage the sufferings of child-birth, whenever this can be done with safety to the mother and child, and while leaving much to Nature, he should be constantly on the alert to see when art can aid her. If, in a severe and prolonged case of labor, we can safely reduce the patient's sufferings and conserve her failing strength, by causing the pains to come at longer intervals, and then to do more efficient work, it is certainly our duty to do so. Chloral, we know, will accomplish much under such circumstances, but let us not forget that electricity may do as much, or more, and with even less risk to our patients.

The needful appliances are, a portable faradic battery, two or three electrodes, and the necessary conducting cords. It is all-important that the battery should be so constructed as to require very little attention while in operation, and also when not in use. It is desirable that the contact-breaker should be capable of nice adjustment, so that the current may be "made" and "broken" evenly; and just here I would say that it would be a great advantage to the obstetrician to have the usual contact-breaker replaced by the new "singing rheotome" which Dr. Hutchinson has devised for the purpose of making very rapid vibrations. This instrument, as I have already said, has only just been brought to the notice of the medical profession, but I feel quite confident that, had I had it at the time I was attending the cases described in this paper, the sedative effects of the current would have been still more remarkable. As, in a general way, it may be said that a current from a coil of coarse wire is the most appropriate for stimulating muscular fibre to contraction, and that from a fine wire coil most suitable for producing sedation, it is desirable to have the faradic apparatus provided with such coils. Where, however, one desires to have a very small battery, which can be carried in the coat-pocket, or in the obstetric bag, some of these refinements must be sacrificed to portability. A very useful machine of this class is the one known as "The Smith & Shaw Closed Cell Battery." It is not nearly so dirty and wasteful as the well-known Gaiffe pocket battery, and is in every respect a much more efficient instrument. The current is sufficient for most cases, but even the coil with two cells of battery is, in exceptional cases, hardly strong enough. It can be carried about charged, so as to be ready for use at a moment's notice. Each charge is sufficient to run the battery for a number of hours, and its renewal is quickly and easily effected.

The best method of applying the current to the patient, is with the positive pole to the sacro-lumbar region, and the negative pole to the abdomen. Fairly good work can be done with two sponge electrodes applied to the abdomen, on either side of the uterus, but this method is not so convenient or so effective as the one first described. The only precaution necessary in regard to the position of the electrodes is to place them so that the current will not pass through the head of the child. The method described will avoid such a danger in vertex cases, but where the breech presents, it is better to apply one pole to the sacro-lumbar region and the other to the nape of the neck.

For the lumbar electrode I use a small copper plate to which is attached the conducting cord from the positive pole of the faradic machine. The portion of the cord near the plate should be covered with rubber tubing, so that it may be easily cleaned. When the electrode is to be applied, it is laid upon a strip of roller bandage, and a thin sheet of wet absorbent cotton is wrapped around both the plate and bandage. The bandage is then fastened around the patient like a belt, and serves to retain the electrode in contact with the skin, and in proper position, even though the patient be rolling about the bed. It matters not if the electrode be soiled with the discharges, for the rubber covered cord and the copper plate are easily cleaned, and fresh absorbent cotton and bandage are used for each case. Unless very powerful currents are required, the best abdominal electrode is the operator's hand, as he is kept constantly informed concerning the strength of the current, and, more important than all, he can keep the uterus in his grasp. This will be particularly appreciated by anyone using faradization in the third stage of labor, for with an ordinary sponge electrode it is a very easy matter for the uterus to relax and escape around one or the other side of the electrode. Where the hand is used, the operator takes an ordinary sponge electrode in one hand, while the other is applied to the abdomen, or the conducting cord from the negative pole is connected to a metal band fastened to his wrist. The objections to this method of application are the weariness it produces in the operator's hand and arm, and the fact that if the current be sufficiently strong to be effective, it is very disagreeable to some persons, who are especially susceptible to its influence. The best substitute for the hand is a flat sponge, insulated at the back with a piece of sheet rubber. In selecting such an electrode, it is important to see that the back is very flexible. Another method is to connect the negative cord with a small metal ball which is placed in the centre of a large sponge. The operator can then grasp the sponge with the naked hand, or can protect his hand with a rubber glove.

Before beginning the application, one should always be careful to see that both electrodes are well wetted with warm water, that the strength of the current is reduced to the minimum, that the contact-breaker is adjusted to work smoothly, and that the current is turned off from the electrodes. Both electrodes are then placed in position, the current turned on, and its strength very gradually increased until it is distinctly perceptible to the patient, but causes no pain. The circuit should be kept closed for ten or fifteen minutes, when the sedative effect should be evident. When this is once obtained, it is only necessary to keep the circuit closed during the pains. When used for its oxytocic effect, the current should be strong enough to be disagreeable, without being decidedly painful, and should be applied intermittently, in imitation of the normal rhythmical contractions of the uterus. When it is desired to employ electricity in the third stage of labor, to facilitate the delivery of the placenta, and to encourage firm uterine contraction, the circuit should be closed as soon as the child is delivered, and a mild current applied to the uterus. Unless it is evident that this will cause the expulsion of the placenta prematurely, the current need not be broken. If the uterine contraction be sluggish, the strength of the current should be rapidly increased, when there will usually be a sudden and powerful contraction, sufficient to expel the placenta. It must be remembered that adipose tissue is a very poor conductor of electricity, and that, therefore, in women with fat abdominal walls the results are likely to be very disappointing, unless powerful currents are employed.

To recapitulate: 1. The necessary apparatus is neither complicated nor troublesome. 2. The application of electricity in cases of midwifery requires no special technical skill, and is, therefore, applicable to the needs of the general practitioner. 3. Electricity exhibits its sedative

effect in parturition sufficiently often to make it worthy of trial where the physician is reluctant to administer chloral or chloroform. 4. Electricity assists labor by increasing the force and efficiency of the natural uterine contractions; it is prompt and reliable, and is entirely under the control of the operator. 5. The use of electricity in the third stage of labor aids the expulsion of the placenta, and diminishes the risk of hemorrhage.

In conclusion, the writer ventures to express the belief that every physician who may be induced to give electricity a fair trial in his obstetric practice will find in it a valuable ally, but one which no more deserves to be considered infallible than do the other remedial agents at our command.

210 WEST 135TH STREET.

HEMIANÆSTHESIA IN FATHER AND DAUGHTER.[1]

BY S. PLACZEK, M.D.,

ASSISTANT PHYSICIAN TO DR. OPPENHEIM'S POLICLINIC FOR NERVOUS DISEASES, BERLIN, GERMANY.

SINCE Charcot, with his faculty for close observation, first placed the subject of hysteria in a new light a numerous body of scientific men have discovered facts upon facts, some of greater, some of less interest. Many of the ideas which had hitherto been held on this subject were found to be untenable, while others were altered, so as to be in accord with the principles of modern psychological thought. Permit me, gentlemen, to present to you the case of a fireman, forty years of age, and his daughter, nine years of age, who are suffering at the same time from hysterical hemianæsthesia, as a slight contribution to the vast subject of hysteria.

The opinion of Lasègue, that hysterical hemianæsthesia is a sympton which must be searched for; and that of Richer, which he expresses in the words "Beaucoup sont anæsthétiques sans le savoir," were confirmed in this case. It was only as an attendant of his sick daughter that the father came to the policlinic, and it was only the accidental examination of his person that led to the discovery of the existence of this strange symptom in him. Before demonstrating this hemianæsthesia I will relate some important facts in the family history.

The father of the patient and the grandfather of the little child, an instrument-maker, was occupied a great deal with metals, as brass, lead, copper, was an excessive drinker, and was always a very nervous man. He made one unsuccessful attempt at suicide, and died from apoplexia cerebri. A younger sister was affected in her youth with convulsions, and suffers now from a nervous irritability, which is increased by the depressing consciousness of a bodily deformity. A younger brother of this girl is a stutterer.

When tested with the brush, there is seen to be an anæsthesia of the left side of the body, sharply defined at the median line. At the same time there is an anæsthesia of the organs of special senses on the same side, so that the patients do not taste with the left side of the tongue, nor smell with the left side of the nose. In addition to this the father has a well-marked concentric narrowing of the field of vision for white and colors in the left eye, and shows the "Förster'schen Verschiebungstypus" in an exquisite manner. In the girl, the acuteness of hearing is diminished, so that whispering is heard only at a distance of one metre from the ear.

If I prick the patient with a pin, or even transfix a fold of the skin, there is no exclamation of pain. The same can be shown in a more convincing manner by the use of "Goldscheider's" method. If the faradic brush is placed in the median line of the body in such a manner that one half is on the sentient side, the other half on the non-sentient side, and the current is allowed to pass through the brush, its strength being gradually increased, the patient suffers severe pain. If now that part of the brush which is in contact with the sentient side be raised, all the pain immediately ceases, although the strength of current is the same and its density is increased.

This symptom of hemianæsthesia, which, according to Charcot, is almost pathognomonic, with involvement of the special senses, would suffice for a determination of the character of the trouble, but there are other symptoms present which add weight to the diagnosis.

The subjective symptoms of the older patient consist in drawing pains, which pass from the calves of the legs to the shoulders, weakness and tremor of the legs, anxiety, irritability, susceptibility of being easily frightened, and insomnia.

The change in the condition of the patient when he passes from a sitting to a recumbent position, is very noticeable. At first he hesitates, his face becomes red, his pulse rate increases from 80 to 138. The slight tremor rapidly increases to clonic convulsions, which in turn pass into a tonic spasm of the muscles, involving all the muscles of the lower extremities. Both active and passive movements of the extremities are impossible when the patient is in this condition. There is also noticed an irregular contraction of the left trapezoides, as a result of which the head is continually drawn backward and toward the shoulder.

If nothing were done to relieve the clonic convulsion of the muscles a considerable period of time would elapse before it would cease spontaneously, but it is by no means difficult to effect this cessation by psychical influence, especially by hypnotism combined with suggestion. The simple momentary fixation of my finger is sufficient to put the patient into a sleeping condition, during which all painful contraction of the muscles immediately ceases. Suggestion during the hypnotic state produces a marked improvement in the condition of the patient, which persists for a considerable period after the hypnotic state has passed away. The reflexes are increased, and "hysterogenic zones" are not to be found.

The nine-year-old daughter of this patient, although anæmic in appearance, enjoys the best of health. Besides the complete hemianæsthesia previously demonstrated, the patient frequently passes into a cataleptic state, in which condition she is always brought to the policlinic. In this state her body is perfectly rigid, consciousness is retained, the movements of the eyes are perfect, the pupillary reaction is prompt, and the corneal and conjunctival reflexes are present. On elevating the patient the trunk is seen to be perfectly rigid. The arms and legs are in a state of hyper-extension and cannot be flexed. The fingers are flexed and closed upon the palm of the hands, and if they are extended they immediately return to their former position. There is no hyperæsthesia of the ovaries, nor is it possible, by pressure in this region, to produce or suppress a cataleptic attack. Neither are there any "hysterogenic zones" to be found.

By the application of the magnet combined with suggestion the cataleptic attack can be suppressed. An aphonia always persists after the cataleptic state has passed away, but this symptom also can be made to disappear by means of new hypnotic suggestion. Once we succeeded in causing the hemianæsthesia to disappear, but it returned in a short time.

Undoubtedly, the common origin of the described hysterical manifestations is to be sought for in the neurasthenic affection of the grandfather. For this, increased by continuous alcoholic excesses and by the pernicious influence of metallic poisons with which he came in contact for many years, tended, no doubt to favor the transmission of a nervous disposition to his offspring. This hereditary taint exerted its strongest influence on the older patient, the first child of the marriage, in whom a typical hysteria has been developed, whereas the second child, the sister of our patient, was only affected by convulsions in her childhood, and later in life suffers from nervous irritability, which, however, is fostered and increased by the

[1] Paper read before the Berliner Gesellschaft für Neurologie und Psychiatrie.

depressing consciousness of her bodily deformity (kyphosis).

The typical hysterical convulsions are absent in this first generation, but the spasmodic tremor of the patient, produced by an altered mental condition, and therefore also capable of being acted upon by psychical influence, can be looked upon as a rudimentary compensation.

It is only natural, and easily to be understood, that a child of this neuropathic man, who drank excessively and was also subjected to the influence of metallic poisons, shows the disease of her father in the most exquisite manner, with all its characteristic symptoms and details. It is an established law that the first-born child suffers most from the hereditary taint, which is well exemplified in the present case.

That heredity acts a prominent part in the production of hysteria, that it is the "cause des causes," as Trélat says, is a fact long ago proved. Daily clinical experience teaches us that every word of Déjérine's view in his celebrated work is to be accepted as true. It reads thus:

"L'hystérie peut être considérée comme la plus héréditaire des névroses; elle affecte des relations intimes avec les états névroses et psycho pathologiques; elle peut s'associer, se combiner avec eux; elle peut en être la transformation, ou à son tour se transformer en eux, montrant peut-être mieux que n'importe quelle névrose, la connexion qui la retient à la grande famille névro-pathologique."

Briquet found that among 100 cases 25 were descendants of parents who suffered from functional or organic diseases of the nervous system. Hammond states that among 209 cases, nervous diseases in the mothers, aunts, grandfathers, or other near relations were found 121 times. Bitault observed in 77 of 100 cases of male hysteria "l'hérédité névropathique." Briquet even goes so far as to claim that "half of all hysterical mothers produce hysterical offspring." The same opinion is held by Bernuk, Féré, Déjérine, etc. The last author is of the opinion that l'épilepsie du père semble être pour la fille hystérique ce qu'est l'hystérie de la mère. Charcot's view, based upon a very strict experience, is that the hysteria of the mother has frequently as consequence the hysteria of the son. But he does not mention that the opposite holds equally true.

Déjérine says that neurasthenia and nervousness of the father manifest themselves in the form of hysteria in the daughter. The simultaneous presence of hysteria in father and daughter he seems not to have observed. Our cases are therefore more interesting, because they are the only ones in which hysteria, with all its characteristic symptoms and signs, has been transmitted from the father to the daughter.

That the hemianæsthesia appears in both patients on the left side is in accordance with the degree of frequency with which hemianæsthesia is found to affect especially this side of the body.

Briquet found among 400 cases of hysteria 93 with hemianæsthesia, of which in 70 the left side was affected, in 23 the right side. Bourneville also supports the above observation, finding the left side affected in 23 cases, the right side in 11.

There is no ovarian tenderness in the daughter, and it is impossible either to check by permanent pressure of this region a cataleptic attack, or to produce a new attack. This observation is opposed to Charcot's view, who seems always to have observed ovarian hyperæsthesia and hemianæsthesia in the same case, so that he treats of both of these conditions in the same chapter.

Allow me, gentlemen, to add some few words on the forensic importance of the present cases. It is hardly to be believed, but is nevertheless a fact, that this poor man, whom every physician of even limited experience would regard as "aegrotissimus vir," has been declared upon expert testimony to be a simulator, and has lost all claims to a pension which he had acquired by a seventeen years service.

How it has been possible to raise the suspicion of simulation in view of all these various symptoms, which can have but one meaning, is for me problematical, but Machiavelli says: "There are many who see, a very few who observe."

My sincerest thanks are due to Dr. Oppenheim for permitting me to publish these cases, and also to Dr. Hermann H. Hoppe for his kind assistance in preparing the article for English publication.

Progress of Medical Science.

Picrotoxine in the Night-sweats of Phthisis.—Dr. d'Amore has published his experience with picrotoxine and atropine in the night-sweats of phthisis. He gives the picrotoxine in granules containing $\frac{1}{160}$ of a grain each. The author reports forty-five cases thus treated. In fifteen advanced cases he gave without success two pills of atropine containing $\frac{1}{6}$ of a grain each daily; in these cases, two to four granules of picrotoxine, continued for several days, relieved the condition very much. In twenty cases, with less pronounced lesions, atropine did well in some and failed in others; but picrotoxine, used for several days, checked the sweating completely. Finally, in ten early cases, the results were equally good from the use of either drug. The writer explains these differences by the cause of the sweating in the several stages of the disorder. In the early stages much of the sweating is due to the action of the secretory nerves, and these are controlled by atropine; later, the sweating is due more to paralysis of the vaso-motors, and as atropine does not act upon these it loses its power, while picrotoxine, which does act upon the vaso motor system, retains its value in the advanced stage.—*Les Nouveaux Remèdes.*

Diarrhœa from Retroflexion.—Dr. Fischel records the case of a woman, aged twenty three, who was seized with violent diarrhœa a few days after recovery from confinement. It commenced regularly between 4 and 7 A.M., preceded by hypogastric pains and a feeling of anxiety. Four or five motions were passed. At the end of three weeks the patient was very emaciated, having lost nearly twenty pounds in weight. No drugs were of service, and rest did no good. Fischel explored the pelvis and discovered retroflexion of the uterus, which to his knowledge had previously lain in its right axis. Following Schauta's directions, the displacement was rectified, and a pessary applied. Next morning the diarrhœa ceased and did not return. Nine months later the pessary became displaced, and the intestinal catarrh returned, but ceased on rectification of the position of the pessary. A year and a half later the pessary was removed with the same result; on its replacement the retroflexion was rectified and the diarrhœa once more ceased.—*Prager Medicinische Wochenschrift.*

A Chlorodyne Drinker died recently in Wales who used to take about five ounces a week of the drug.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, December 24, 1892.

A MODERN ASYLUM SUPERINTENDENT'S VIEW OF THE CARE OF THE INSANE.

A PAPER on the "Care of the Insane," by Dr. Richard Dewey, of Kankakee, Ill., presents in a very complete way some of the modern views on the subject which are deserving of consideration. The conclusions reached show a very striking difference in the attitude of the asylum superintendents to-day from what it was ten years ago.

One of the new ideas in asylum construction is that regarding the character of the buildings and their cost. Instead of the old Kirkbride system of a central executive building and many-storied wings for patients, the whole forming a massive, striking, and expensive structure, the modern plan is to construct numerous detached buildings resembling comfortable homes. Here the patients are grouped in accordance with their form of insanity, social condition, etc. The cottage- or colony-plan for the insane has another advantage, that the buildings can be erected at about one-half the expense of the old style. Already there are as many as five thousand insane provided for in the new way. It is safe to say that the new Bloomingdale Asylum building, now in construction at White Plains, will be the last example of the old style of insane asylum.

Dr. Dewey believes that the insane should be in the care of the State rather than the counties, and he advocates an unpaid Board of Commissioners of Lunacy with advisory powers, rather than a paid commissioner with mandatory powers. It has been found in this State that some body or person with State authority has been needed to control properly the numerous private institutions which are started and run purely for commercial purposes, and often with little regard to anything but business interests. If an advisory board were sufficient to prevent abuses in this direction, it would be the best method of supervision. Already a great deal of friction and ill-feeling have been aroused by the exercise of the somewhat arbitrary powers of the present commission. The time will come when an unsalaried supervisory board will be demanded, and will probably do the work of a paid commission.

Dr. Dewey is, we believe, one of the first of asylum superintendents to recommend the appointment of a woman physician on the medical staff of large insane asylums. He makes this recommendation, although he does not "ignore the fact that greatly exaggerated ideas of her possible usefulness have been entertained in many quarters, and that experience has shown that far less was to be expected from local treatment and operative procedure, in certain classes of the female insane, than had at first been supposed."

We have always claimed that when an asylum superintendent found that a woman physician could help him in the medical care of the insane, such a person should be employed. It is the indiscriminate legislating of women into office, on the ground of sex alone, which we strongly oppose.

CASTRATION FOR MELANCHOLIA.

THE operation of castrating males for nervous and mental disorders is at last put upon a firm clinical basis. Oöphorectomy came from the South, and thence diffused its genial and unsexualizing influence over the East and North, but testectomy, if we may coin a word on so great an occasion, comes from the West. It was in 1891 that the Eastern Michigan Asylum published an annual report containing the history of a case in which the operation of castration was done for the relief of a "sickening neuralgia" of the testicles. The patient had not only neuralgia, but melancholia. One of the testicles was removed, and the testicle was found diseased, but not, as we understand the description, cystic or suppurating. The patient improved, but was not cured, and so, later, the second testicle was removed. The medical superintendent, Dr. Burr, now reports that the cure is complete. It is interesting to notice that both testicles had to be removed, just as, in the opposite sex, we are told that both ovaries ought to go in order to get the best results.

Here we have a case of chronic neuralgia and melancholia, in a man of fifty-seven, cured by castration. Neuralgia is very common, and so is depression of spirits. There is a fruitful field, therefore, in which ambitious andrologists may work. Shall we not soon begin to get reports of "my second series of one thousand castrations, with hints on technique?"

CRIMINAL TREATMENT OF CHOLERA.

UNDER this heading the *Correspondenzblatt für Schweitzer Aertzte* refers to two cases of cholera treated on surgical principles, both promptly dying. The physician whose fertile brain devised the new method is a Belgian, Lambolle by name, and was so proud of his brilliant achievement that he made it public in No. 46 of the *Semaine Médicale.*

The method of procedure was briefly as follows: 1. Laparotomy, which is the recognized stepping-stone to surgical fame. 2. Attaching the presenting knuckle of intestine to the abdominal wound. 3. Opening of the intestine. 4. Introduction of rubber tubing into the bowel. 5. Irrigation of the bowel in distal and proximal directions by sublimate solution (1 to 3,000).

After this slight surgical interference the patients received coffee and peppermint tea. The temperature then rose, the pulses became perceptible, they ceased to vomit and defecate, and—died. But the operation was successful, although there was no time for union by first intention.

What next will the ante-mortem laparotomist attempt "under antiseptic precautions?"

MEDICAL CENTRES.

PHILADELPHIA is justly proud of its medical institutions, and we rejoice to learn of their present prosperity. According to a recent census of matriculates (*Medical News*) there are now in attendance at the various regular medical schools, 1,774 students. The expansive fancy of the editor of the *News* is led to speak of this number as 2,000; and it is close upon it. Three years ago Philadelphia had but 1,286 students, and at the present rate of increase the 2,000 mark will be reached in a couple of years. Our esteemed contemporary is therefore only two years beyond date.

We are unable to give this year's statistics of the New York schools, but three years ago we had 2,146 matriculates, not counting 234 homœopaths, eclectics, and students of the Druidic Banchoreion. The number at present of regular medical students is estimated to be over 2,300, not including 1,000 physicians attending the post-graduate schools. New York is perhaps holding its own, but Philadelphia is following close upon us.

The town of Chicago, of which some people may have heard, had in 1889–90, 871 regular medical students, and 426 homœopaths, eclectics, physio-medicals, and other variations of the type.

THE COMFORT OF PHYSICIANS.

AT intervals during the coming year it is proposed to issue supplements to the MEDICAL RECORD, devoted to everyday phases of professional life which do not come within the strictly scientific sphere of the journal. Although the hardest-worked class among educated men, physicians give too little attention to securing comfort, rest, and relaxation, and an effort will be made at least to suggest methods of alleviating the hardships of the daily routine, and of using every advantage of modern civilization.

From time to time the subjects to be treated of in the succeeding supplements will be announced, and our subscribers are cordially invited promptly to send us any communications which their knowledge or personal experiences may suggest.

The first supplement of this series will appear early in 1893, and will be devoted to methods of conveyance, embracing every form of vehicle used by physicians, horses, clothing for man and beast, creature comforts, medicine-chests, saddle-bags, and office furniture.

An Old Family Mansion on lower Fifth Avenue, occupied by the late Dr. Frederick Bedford, has been torn down to make place for a large business establishment. The property was purchased in 1848 by Dr. Bedford's distinguished father, Dr. Gunning S. Bedford. He had at that time founded the medical school of the University of the City of New York, and had established the first clinic exclusively for women in the world.—*Boston Medical and Surgical Journal.*

The Highest Court of Germany has decided that legal human life dates from the beginning of labor, and that its destruction before full term is not murder. This decision opens a wide avenue of criminal possibilities.

News of the Week.

The Cholera still lurks in various parts of Europe. In the last week of November sixteen deaths occurred from cholera in Holland, and since then three fatal cases are reported from Gastel, in North Brabant, and one fatal case at Weesp, in North Holland. At Buda-Pesth the fresh cases now average two or three, with one death, daily. There have been several fresh cases of cholera, with two or three deaths, at Dunkirk and in the surrounding villages. The *Débats* publishes a telegram from Cherbourg, of November 29th, announcing the presence of the disease at that place and some of the neighboring villages, and of two fatal cases at Gonneville. Cases are still reported in Hamburg. Ninety-six cases were recently reported in Russian Poland within three days.

Murdered with a Sponge.—At a recent meeting of the Société de Médecine Légale an interesting communication was made, on behalf of Professor Cazeneuve, on a singular case of infanticide involving a somewhat unusual medico-legal problem. It was a question concerning an infant of five months, which had died suddenly in 1891 without showing any previous symptoms of disease. At this time there was no suspicion of crime, and it was only owing to certain rumors, sixteen months later, that the police took action and caused the body to be exhumed. The chemical analysis for traces of arsenic, lead, mercury, and other poisons came to nothing. However, further research led to the discovery of eight small pieces of an elastic blackish-gray substance blocking up the intestinal tract. After repeated washings and careful examination these were recognized as portions of sponge, and M. Cazeneuve was of the opinion that the ingestion of these fragments of sponge was the cause of death. In support of this opinion he cited the custom which obtains in certain country districts of killing stray dogs and predatory cats, by placing in their way small pieces of sponge soaked in grease, which, upon being swallowed by the animals, become swollen in the intestinal canal, after the manner of a sponge-tent, and thus induce fatal obstruction. Founding an opinion on these considerations, and also taking into account the fact that the portions of sponge presented a well-defined cut surface, the medical jurist concluded that circumstantial evidence was established that the child was caused to swallow the pieces of sponge in a vehicle such as milk or soup. The jury also took this view, with the result that the accused was sentenced to penal servitude for life.—*The Lancet.*

Alumni Association of Charity Hospital, New York.—The following officers have been elected for the ensuing year: *President*, W. L. Carr; *Vice-President*, R. C. Newton; *Secretary*, Alexander Lyle; *Treasurer*, Arthur T. Muzzy.

Dr. Francis Upton Johnston, of New Brighton, died at his home, recently, aged sixty-six years. Dr. Johnston was a graduate of the College of Physicians and Surgeons, and practised medicine in this city for several years.

Rectal Feeding may be carried on by means of a mixture of two eggs, twenty grains of pepsin, ten grains of chloride of sodium, and six ounces of water (*Detroit Emergency Hospital Report*). This mixture should be

slightly warmed, thoroughly agitated, and then gently introduced into the bowels by means of a syringe. To facilitate the entrance of the fluid into the intestines, it is well to put the patient in a position with the hips much elevated above the head; either the knee-chest position, or with two or three pillows resting beneath the hips.

Dr. Montgomery Jones died on December 18th, at his residence in Fort Edward, aged forty-five years. He was born in Rock Island, Canada, educated at McGill College, and practised in Sherbrooke and Chicago.

To Abolish the Death Penalty.—A very determined effort will be made this winter to have the Legislature repeal the section of the Penal Code relative to the infliction of the death penalty, and have adopted in its stead a life imprisonment section, as the severest penalty to be inflicted for murder in the first degree. Some of the strongest advocates of abolition of the death penalty are returned to the Legislature this year, and it is intimated by those who intend to press the matter that Governor Flower is not averse to its adoption, and in fact favors it. The proposed bill will take from the Chief Executive the power of pardon, and allow pardons to be granted by the court alone, upon the presentation of new evidence of an extenuating nature. There are at present eleven murderers in the various State prisons awaiting death, but the repeal of the law could not be effected in time to save any of these men, and, in fact, could not in any event, as it would not be retroactive.

The Late Mr. Colles, of fracture fame, is to have a memorial portrait in the Royal College of Surgeons at Dublin.

The Anti-tuberculous League of France has distributed over 2,600,000 circulars giving information how to prevent tuberculosis.

The Comma Bacillus of Cholera cannot live in caviare, says Professor Fraenkel; it dies very quickly on tobacco leaves.

Berlin has one hundred and eighty-three "Policlinics," so called, and the thing is getting to be overdone; the policlinics are really only private dispensaries.

The Number of Drug Stores in the United States is said to be 34,000, of which 10,649 are in the Eastern States. This makes about one drug store to every three doctors, and one to 1,700 of inhabitants.

Children and the World's Fair.—The Board of Lady Managers of the Columbian Exposition has undertaken to build and equip a structure devoted to children and their interests. A series of manikins will be so dressed as to represent the manner of clothing infants in the different countries of the world, and a demonstration will be made of the most healthful, comfortable, and rational system of dressing and caring for children according to modern scientific theories; while their sleeping accommodations, and everything touching their physical interests, will be discussed. Lectures will also be given upon the development of the child's mental and moral nature by improved methods of home training. There will be a crèche for babies and a play-ground for children.

The Family Physician Syndicate.—A company has been organized in Cincinnati, according to the *Lancet-Clinic*, which proposes to give, to those families who desire such protection, an absolute and sure method of providing a physician and surgeon of the highest professional standing, for sickness and accident, to any and all members of the family. The company also provides all the medicine necessary in such cases. The company also provides all medical and surgical appliances necessary in the treatment of these cases. The cost is from $15 to $20 a year, according to the size of the family. The *Lancet-Clinic* is much scandalized by the appearance of this company; but it seems to be only an enlargement, with a good deal of attendant noise, of the provident-dispensary and club-doctor system.

Professors von Pettenkofer and Emmerich have followed the example of a Paris physician and swallowed cholera cultures. They took bicarbonate of soda at the same time, in order to neutralize the acidity of the stomach, and they disordered their digestion by imprudent diet; but they did not get cholera. Von Pettenkofer's experiments have served the purpose of showing the importance, in development of cholera, of the proper soil. They do not disprove, however, the established fact that the comma bacillus is an essential to the disease.

Wire Mattresses in Lodging-houses.—At a meeting of the Board of Health, held December 7th, Dr. Joseph D. Bryant, as Chairman of the Sanitary Committee of the Board, recommended that all the lodging-houses in the city should be equipped with wire mattresses, to take the place of the textile mattresses now used. He also advised that in every lodging-house there should be provided a room for isolating lodgers suffering from, or suspected of being affected with, contagious diseases. The Board of Health has ordered that after April 1, 1893, wire mattresses and isolating be required for lodging-houses.

The Sixth Annual Meeting of the National Association of Railway Surgeons, embracing the United States of America, the Dominion of Canada, the Republic of Mexico, will be held at Omaha, Neb, the last Wednesday, Thursday, and Friday of May, 1893. The general subject for discussion will be "Injuries of the Cord and its Envelopes without Fracture of the Spine."

A Faithful District Physician.—In the Annual Report of the Post Graduate Hospital the following interesting incident is cited: "Some time ago the District Physician was called hastily to see a young man who was thought to be dying. After careful examination it was determined that he was suffering from appendicitis, and the only chance the young man had of life was an immediate operation. The doctor ordered a cab, carried the young man down three flights of stairs in his arms, and had him admitted to the hospital at ten o'clock at night. One of the attending surgeons was hastily summoned, and decided that it would be safe to wait until morning before operating. The following morning he was operated upon. For several days his life hung in the balance, but he made a good recovery and is now perfectly well. He must, necessarily, have died had it not been for the prompt surgical interference."

Another Bill for National Quarantine.—Mr. Brosius (Rep., Pa.), introduced a bill to provide for the improvement of the Federal quarantine service and for the tem-

porary suspension of immigration. It empowers the Secretary of the Treasury to establish Federal quarantine stations at Portland, Me., Boston, New York, Philadelphia, and Baltimore, and to put them in condition to prevent the introduction of contagious or infectious diseases. The stations shall be under the control of the Marine Hospital service. The Secretary of the Treasury is authorized to select plans for the erection of quarantine buildings. It is further provided "that for the security of the people of the United States against the introduction of Asiatic cholera, all immigration from European and Asiatic countries shall be suspended for one year from the passage of this act." Seven hundred thousand dollars is appropriated to carry out the provisions of the measure.

Obituary.

SIR RICHARD OWEN,

LONDON, ENGLAND.

Sir Richard Owen, the anatomist, died in London, December 9, 1892. He was born at Lancaster on July 20, 1804. He received his early education in his native town, and at the age of twenty he began a medical course in the University of Edinburgh. He completed his studies in London and Paris medical schools. When thirty years old he was appointed to the chair of Comparative Anatomy at St. Bartholomew's Hospital, and two years later he succeeded Sir Charles Bell as Professor of Anatomy and Physiology in the College of Surgeons. He held the latter place for twenty years, leaving it only to take charge of the Department of Natural History in the British Museum. He had the cross of the Legion of Honor, was a chevalier of the Prussian Order of Merit, and was one of the eight foreign associates of the French Institute. He was created a Commander of the Bath in 1873, and subsequently was made K.C.B. He wrote voluminously. Among his works are: "On the Nature of Limbs," "Lectures on the Comparative Anatomy of the Invertebrate Animals," "History of British Fossil Reptiles," "On the Gorilla," "On the Dodo," and "The Fossil Reptilia of South Africa."

WATTS C. LIVINGSTON, M.D.,

NEW YORK.

Dr. Watts C. Livingston, died December 19th at Green Cove Springs, Fla. He was born in Dutchess County seventy-three years ago. At the age of twenty he became principal of an academy in Seneca, and while there married Eleanor Palmer. Two years after he removed to Cortland, where also he conducted an academy. In 1849 he came to this city and entered the College of Physicians and Surgeons. He was graduated in 1852, and was appointed on the medical staff of the New York Hospital, where he served for a year and a half. He was a professor in chemistry in the public schools for several years. Dr. Livingston was a member of the Academy of Medicine, the Pathological Society, Physicians' Mutual Aid Society, and the Physicians' Medical Aid Association. His wife died last March. He leaves a daughter, the wife of Dr. J. Scott Aitken.

The New York College of Pharmacy, located since 1879 on East Twenty third Street, which has for some time past been contemplating a move uptown, has now secured a plot of ground, 75 by 100 feet, on Sixty-eighth Street, between Columbus Avenue and the Boulevard, and will erect a handsome and commodious building upon it.

Reviews and Notices of Books.

The Pocket Pharmacy, with Therapeutic Index. A Résumé of the Clinical Applications of Remedies Adapted to the Pocket-Case, for the Treatment of Emergencies and Acute Diseases. By John Aulde, M.D., Member of the American Medical Association, of the Medical Society of the State of Pennsylvania, of the Philadelphia County Medical Society, etc. New York: D. Appleton & Co 1892.

This work is, as the author explains in the preface, in the nature of a plea for small doses to be administered in accordance with physiological deductions. The pocket-case which the author recommends contains twenty-four drugs, and the book consists of a brief statement of the therapeutic indications of each of these remedies, taken up in order. Dr. Aulde is a firm believer in the efficacy of small doses of drugs and writes with all the enthusiasm and confidence of one who has proved the soundness of his faith by the crucial test of experience. Whether others whose faith in the value of drugs is less implicit will meet with equal success can only be shown by trial. The author himself says that "physicians who adopt this plan for the first time will be surprised at the prompt effects secured from medicine, but they will be more astonished at the number of ailments which can be met by this small number of drugs." We think it would have been better had the author adhered to his original plan of giving brief notes indicating the physiological actions of the drugs.

The Principles of Theoretical Chemistry, with Special Reference to the Constitution of Chemical Compounds. By Ira Remsen, Professor of Chemistry in the Johns Hopkins University. Fourth Edition. Thoroughly Revised. Philadelphia: Lea Brothers & Co. 1892.

This book is one of great utility to the student of chemistry in that it explains to him, as far as may be, the theories of chemical action and points out the grounds upon which these theories rest. There is yet much that is inexplicable in chemical action, and doubtless the prevailing theories will be modified as a result of further investigation and discovery, but it is obvious that no advance can be made except along the present lines; one must be familiar with what is now accepted and with the reasons for this acceptance before he can point out insufficiencies of current explanations of chemical phenomena or bring forward others to take their place. The object of the author of this work is stated to be to help students to get clear ideas in regard to the foundations of chemistry, and anyone who will study the treatise conscientiously must acknowledge that this object has been achieved. That it has met a want is shown by the fact that the four successive editions have followed one after the other at brief intervals of time.

An Illustrated Encyclopædic Medical Dictionary. Being a Dictionary of the Technical Terms Used by Writers on Medicine and the Collateral Sciences, in the Latin, English, French, and German Languages. By Frank P. Foster, M.D., Editor of the *New York Medical Journal*, Librarian of the New York Hospital. Vol. III. New York: D. Appleton & Co. 1891.

This volume of Dr. Foster's incomparable dictionary carries the work along Fascia to Minjak-Lazam. If any of our readers ask what minjak-lazam signifies we must refer them to the dictionary, where they will find it fully explained. Indeed it would be difficult to find in this book any omissions of words employed in medicine, and one puzzled by any term met with in his professional reading may turn to the work with confidence that the word will be there explained. The dictionary is, we fear, too bulky for everyday use by the average practi-

tioner, but it should nevertheless be in every doctor's library, to be used as a work of reference and a court of last appeal when other authorities disagree. It is a scholarly work of which the learned editor may well be proud.

INDEX CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, U.S.A. Authors and Subjects. Vol. XIII. Royal octavo, pp. 1005. Washington, D. C.

THIS volume is of the size corresponding with the previous ones, and commences with Sialagogues and ends with Sutugin. It includes 9,751 author titles, representing 4,213 volumes, 6,806 pamphlets, 13,498 subject titles of separate books and pamphlets, and 29,896 titles of articles in periodicals. It is edited, as have been the former volumes, by John S. Billings, Surgeon, U.S.A.

A MANUAL OF ORGANIC MATERIA MEDICA. Being a Guide to Materia Medica of the Vegetable and Animal Kingdoms, for the use of Students, Druggists, Pharmacists, and Physicians. By JOHN M. MAISCH, Ph.M., Phar. D., Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy. Fifth edition. With Two Hundred and Seventy Illustrations. Philadelphia: Lea Brothers & Co. 1892.

IN the present edition of this standard work the author has retained all the excellencies of the previous editions but has increased the utility of the manual by indicating the accented syllable of the systematic names of plants and animals. Some minor changes in typography, all in the way of improvement, have been made and a number of new illustrations have been added. The illustrations are, many of them, artistically executed and should be very helpful to the student who has not actual specimens of the crude drugs before him. As a text-book for students and as a work of reference for physicians and pharmacists the manual is of great value and well deserves the position it holds as a standard text book of organic materia medica pure and simple, unconnected with therapeutics.

A TREATISE ON DISEASES OF THE NOSE AND THROAT, in Two Volumes. By FRANCKE HUNTINGTON BOSWORTH, A.M., M.D., Professor of Diseases of the Throat in the Bellevue Hospital Medical College, New York, etc., etc. Volume II. DISEASES OF THE THROAT: With 3 Colored Plates and 125 Woodcuts. 8vo. Pp. 809. New York: William Wood & Co. 1892.

THIS, the second and concluding volume of Bosworth's text-book on diseases of the nose and throat, appears two and a half years after the first volume. It is divided topographically into three sections—the first is devoted to diseases of the fauces, including the oro-pharynx, soft palate, faucial pillars, and tonsillar regions; the second to diseases of the larynx; while the third, a shorter section, embraces the grave surgery of the larynx and pharynx; it is to the third section that the colored plates apply.

The author's anatomical descriptions are brief and to the point, his physiological reasoning is simple and scholarly. Under the head of "The Function of the Tonsil" the author states unequivocally that these bodies are largely absorbent, and not secretory; and that the so-called crypts of the tonsil are practically large tubular glands, and, as such, are designed for absorption.

Under the head of "Acute Pharyngitis" the author inveighs against the favorite practice of using astringents by means of the fruit-paste, or sugar lozenges, so current in England and in this country. The stomach and pharynx are in intimate sympathy, and the basis of these lozenges is nauseating. He prefers, when such a form of medication is used, to make a base of extract of licorice, as more agreeable and palliative.

Complete and thorough tonsillotomy is advised, when the necessity of this operation arises, and to this end Mathieu's instrument is preferred, on account of its bident harpoon, its long vertical, rather than antero-posterior fenestra, and the ingenious manner by which the tonsil is slightly drawn away from its bed. The author quotes the definition given in the "National Medical Dictionary," Philadelphia, 1890, of "tonsillotome," viz., "an instrument for slicing off a portion of the tonsil"—as delusive and misleading.

Great stress is laid upon the local treatment of the fauces in diphtheria, if one has fought successfully against the septic poison for twenty-four or thirty-six hours. More can then be done to prevent imbibition of the local septic process by active local measures than by any other mode of treatment. Preference is given to the salts of iron, and of these, first of all, the liquor ferri persulph. and the liquor ferri perchloridi; these diluted with alcohol and applied, under good illumination, on a probe. Next to iron the author places lactic acid, applied locally, in a fifty per cent. solution. The operations of intubation and tracheotomy in diphtheria are given much space. It will be a surprise to the unlearned to read Dillon Brown's statistics of 2,372 intubations with a recovery of 27.2 per cent., while the recovery from tracheotomy was 27.14 per cent. according to the same compiler. This is not the occasion to estimate the advantages or disadvantages of intubation, which has become so popular. The author reviews Bourdillot's statistics of the two methods, and concludes that intubation performed on children under two years of age gives a gain of 12.5 per cent.; between two and two and a half years, a gain of 12.5 per cent.; between two and a half and three and a half years, a gain of 11.9 per cent.; between three and a half and four and a half years, a gain of 3.7 per cent.; between four and a half and five and a half years, a loss of 6.7 per cent.; and over five and a half years, a loss of 2.2 per cent. The present mode of intubation must be accredited to O'Dwyer, of New York, though the idea of inserting a tube into the windpipe for the relief of dyspnœa dates back to Hippocrates.

Tuberculosis of the fauces and of the larynx are placed in their proper sequence by the author—that is, both are manifestations of acute miliary tuberculosis. On this point the views are broad, and will meet with approval by the profession. Cases of local tuberculosis may be endured, and may be cured; but they must be regarded as forerunners of a systematic lesion, which sooner or later will express itself. Palliative rather than astringent measures are recommended, while inhalations of steam and of hot medicaments are not advised. The author places his main reliance in treating tubercular ulceration of the fauces and larynx upon such palliatives as cocaine, morphia, iodoform, etc., but does not feel that he has done his duty without administering lactic acid locally, as recommended in diphtheria, and claims that the two plans are not antagonistic. The author emphasizes the virtues of creosote in small doses, progressively increased, within fixed limits. He doesn't favor doses as high as forty and fifty grains a day.

Chapter XXI., on "Neuroses of the Fauces," is admirably written, but is all too short—only twenty-three pages being devoted to it. These affections are classified as: 1, Abnormalities of Sensation; 2, Neuralgias; 3, Reflex Neuroses; 4, Spasmodic Disturbances, or Chorea; 5, Myopathic Paralyses; 6, Bulbar Paralyses, or Paralyses due to central lesion.

It is unnecessary to more than indicate the salient features of a text-book so admirably equipped as Dr. Bosworth's second volume. There is an independence of opinion and a broad view of disputed points which do not clash. Firm convictions carry weight to the beginner in laryngology, and confirm the well known beliefs of the author with his colleagues.

Both author and publishers are to be congratulated on the good appearance of the book, and on the quality of its illustration.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 1, 1892.

A. L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

Diagnosis and Treatment of Cholera on Swinburne Island.—DR. JOHN M. BYRON read a paper on this subject. He gave the number of the cases on the different ships, and the dates of their departure and arrival, which had brought cholera over from Europe during the fall. The total number of cases of cholera on Swinburne Island had been seventy-four, besides a number of suspects. There were twenty deaths, two occurring within two hours. There were some deaths also from bronchopneumonia, and a limited epidemic of measles. To establish beyond doubt the nature of the disease, a series of bacteriological observations were made on the island, and comma bacilli were found. With few exceptions the malady was of the more serious type. The small number of evacuations, however, was a feature to be noticed. The majority of cases of death occurred during the period of asphyxia; rigor mortis, as usual in cholera, set in early, with muscular contractions, throwing the body into strange attitudes.

Treatment.—The prophylactic measures adopted proved to be the most powerful means of controlling the disease; they were able to stop the cholera in affected ships within the period of five days. The affected ship was visited twice a day, and all suspected cases removed; if necessary a midnight call was made. The water which the ship brought over was all pumped out, the tanks cleansed and disinfected, and a fresh supply of water substituted. The ship's surgeons were instructed to allow no water to be used until it had been boiled, to burn all the food brought by the immigrants, bathe the passengers in sea-water, disinfect the clothing, and hoist a yellow flag as soon as a case occurred on board. The details of disinfecting the steerage, etc., were mentioned.

The treatment of Asiatic cholera was based on a knowledge of its cause. There was a germ which gained access to the intestine and produced a toxicant. On this basis several methods of treatment had been approved by high authority, to which the author referred, such as the use of calomel during the premonitory stage, bichloride, salol, etc. Medicine given, however, to reach and disinfect the intestine seldom accomplished the object; intestinal irrigation seemed to answer this purpose much better. It had been objected that fluid would not pass beyond the ileo-cæcal valve, but this had been disproved by various experimenters, and at Swinburne Island. Saline injections were also made into the circulation, and in only one case did an abscess result. Hypodermoclasis produced effects which were wonderfully beneficial. The vomiting was stopped by giving small pieces of ice, carbonic water, and champagne. The stomach-pump was sometimes employed, and the stomach washed out with a slightly acidulated solution. Inhalation of oxygen had proven useful. The diet had consisted mostly of milk, carbonic water, champagne, and beef-tea, when the stomach would permit. Out of the total of seventy-four cases of cholera, twenty had died, six within two hours after being attacked; three had died from complications. This was considered a very low percentage when it was remembered that usually one-half of all patients died during cholera epidemics. There was room, however, for improvement of the methods used at Swinburne Island.

Personal Experience with Cholera during the Late Epidemic of Cholera at St. Petersburg and Hamburg.—DR. ELMER LEE, of Chicago, read a paper with the above title. (See previous issue.)

Disinfection during the Cholera in Hamburg and Berlin.—DR. AUGUST SEIBERT, in a paper with this title, gave the results of his observations on disinfection against cholera, and also other contagious diseases, in Berlin during the few months past, and stated wherein the method was varied somewhat at Hamburg. The subject was divided into disinfection at the patient's home, hospital disinfection, and the use of heat and steam at stations. Home disinfection was employed in cases of cholera, typhoid fever, diphtheria, and some of the other infectious diseases. A corps of workers was sent with all necessary apparatus in satchels, and every step was carried out in the most scrupulous and detailed manner. The disinfectants employed, besides cleanliness, were milk of lime, carbolic acid, and corrosive sublimate. The proof of the efficiency of this method had been shown in the fact that in Berlin not a second case of cholera had developed in a house in which a patient had been taken ill or died. In Hamburg the proof of its value had not been made so simple and clear, for the reason that the disease there had been spread through the infected water of the river Elbe. Dr. Seibert took occasion to disabuse the impression in the public mind, here created through newspaper reports, that Hamburg was a dirty city. He stated that no street there was as filthy as Third Avenue, and the tenements in New York could not be compared in cleanliness with those in Hamburg.

DR. DE LAND, of Philadelphia, who had also had some experience with the cases at Swinburne Island, spoke of the value of intestinal irrigation and hypodermoclasis, and showed the apparatus which was there employed. It consisted of a fountain with rubber tube, and to the latter they attached an œsophageal tube with two side-openings near the distal end, which was introduced as far up the gut as possible.

DRS. SEIBERT and BYRON wanted to know in what respect Dr. Lee claimed originality for his practice. They insisted that it was essentially the same as that used by Cantani in 1865, and to which special attention was again called in 1884. Cantani used an acidulated solution which they believed was better than soap-suds, because the cholera germ required an alkaline fluid for its existence.

DR. LEE said that so far as he had witnessed the injections made by others, only about one quart of water was used, which was a very different thing from flushing the gut with as much as three gallons, as he practised it.

The other speakers said Cantani's method also implied the use of large quantities of the fluid.

This meeting having been under the charge of the Section of Public Health, Dr. Chapin, chairman, the section elected new officers: *President*, Dr. S. T. Armstrong; *Secretary*, Dr. F. H. Dillingham.

More Scientific than Clean.—German physicians and surgeons, in their own country, are the most pronounced in the profession on the subject of antiseptic treatment of disease, and antiseptic surgery. They have outdone Lister many-fold in their attention to aseptic and antiseptic precautions. Their invention of antiseptic applications, and their attention during operations, in the way of dress and sterilizing apparatus, to all the details that tend to the destruction of bacilli, are to some even painfully painstaking and minute. Yet, with all the theory and practice of the profession, in Germany, on this subject, the people are far behind the English (we won't say the Americans, lest we be suspected of egotism) in real sanitary science. The sewerage of their towns is notoriously defective. The smells that come from their narrow streets are appalling even to a New Yorker, who may be supposed to be pretty thoroughly accustomed to smells and dirt. And the arrangement of their domestic hygiene, in their great buildings, in their hotels, especially as to baths and lavatories, leaves very much to be desired. In other words, unpleasant as it may sound, the English race, as it appears to the average traveller, is a much cleaner one than the German, although the latter is far more scientific.—*Post Graduate.*

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, December 2, 1892.

CHARLES L. DANA, M.D., PRESIDENT, IN THE CHAIR.

Extensive Laceration of the Wrist; Good Result.—DR. CHARLES MCBURNEY presented a boy, eight years of age, as an example of excellent result after very extensive division of the soft tissues of the wrist by a broken bottle, in April. Everything was divided down to the bone except the radial artery and flexor carpi radialis; all the other tendons, and the ulna and median nerves, were separated. His house-surgeon, Dr. Blair, reunited the tissues almost immediately after the accident. The ulna and the median nerves were each brought end to end by four catgut sutures. The return of sensation had been, in Dr. McBurney's experience, remarkably early, being nearly complete at the end of five weeks. It seemed perfect at the present time. Unfortunately the boy left off treatment for some time and complete extension was somewhat delayed, but he was now, under massage and electricity, rapidly regaining perfect use of the hand.

Trephining for Cranial Injury.—Dr. McBurney also presented a boy, about sixteen years of age, who had had a weight fall on his head in June, 1891, causing an extensive scalp wound. He was taken to one of the city hospitals and the scalp was sutured, but nothing was done to the skull. He was unconscious for about two weeks, had right hemiplegia several weeks, and about three weeks after the scalp wound had healed, had a convulsion which affected, as he described it, the right side. He left the hospital, and had about ten or twelve convulsions during the year. The convulsions then showed a localizing character, affecting the right hand, fore arm and upper arm, occasionally the right side of the trunk and right leg; the face never. At first speech was interfered with considerably, but at present very little.

The convulsions were increasing in frequency and the boy was sent to him for treatment. He depended upon Dr. Starr for localizing the centre of cortical irritation. There was a linear scar at one point, and at another a slight irregular depression of bone about two inches by one and one-half, which, however, did not correspond to the centre of cortical irritation as pointed out by Dr. Starr. Although tempted to operate at the site of depression, he did not, but followed Dr. Starr's diagnosis and trephined just behind the fissure of Rolando, taking out about an inch of bone. Directly beneath he found a depressed piece of the inner table buried in the dura mater, and evidently compressing or impinging upon the surface of the brain. When it was removed the brain was seen to be slightly injured beneath. The surrounding bone was slightly depressed, but there was no reason to believe that the brain had been further injured, and the opening was not enlarged. Sufficient time had not yet elapsed to say whether the convulsions had been cured. He presented the case as one in which the objective indications for trephining at a particular place were extremely plain and yet entirely worthless, while the subjective indications were perfect.

DR. BRYANT referred to two cases in which he had sutured divided tendons and nerves with satisfactory result, as far as could be determined during the short stay the patients were under observation.

THE PRESIDENT thought physiology taught us to-day that, where divided nerves were sutured together, the restoration of function was not due to what could strictly be called anatomical reunion of the severed parts, but to a form of anastomosis. He must confess, however, that the method in which function was restored was somewhat obscure in his own mind.

DR. WEIR remarked, regarding the second case, that it was a most instructive one regarding localization and successful removal of an irritating object. He must say, however, that the results of operations for epilepsy, even of the Jacksonian form, were very disappointing.

DR. BRYANT said this patient was in Bellevue Hospital last winter, and he was about ready to operate for the epileptic convulsions when the boy made his escape.

Neurectomy of Trigeminal Nerve at the Foramen Ovale by Sulzer's Method.—DR. R. F. WEIR presented a man, aged fifty-two, who had been a sufferer from tic-douloureux for thirty-seven years. In 1880 the infra-orbital branch of the trigeminal was removed nearly up to the foramen rotundum by Carnochan's method, *i.e.*, by going through the antrum anteriorly and posteriorly.

In 1882 his inferior dental nerve was divided by Dr. Seguin within the mouth, just above the dental foramen.

Relief of pain was obtained for three years. Since then great agony has been experienced until June last, when examination having shown that most of the pain was experienced along the cheek and side of the nose, though some existed also along the auricular temporal distribution, another operation was decided, after conference with Dr. Starr, to expose, in the temporal region above the zygoma and cutting across the temporal muscle, the base of the skull, when by peeling off the tissues with the handles of the scalpel or periosteal scrapers, the foramen rotundum was brought into view. The operative field was widened by division of the zygoma, just in front of the articular eminence and also at the malar junction. This allowed the divided temporal muscle to be materially depressed. The nerve was seized with a forceps and cut off flush with the base of the skull. Only a small portion could be removed and no regeneration of it forward was recognized. The wound of the muscle was closed by silk-worm-gut and the replaced zygoma held in place by similar sutures through the divided periosteum. Rapid recovery took place with primary union. While, however, arrest of the pain of the cheek and nose occurred, yet the neuralgia of the inferior branch of the nerve decidedly increased. This was at first attributed to the handling that the nerve received at the time of the last operation, for it also then came well into view. This neuralgia, however, persisted and increased during the summer, extending to the teeth of the lower jaw. In September the wound was reopened along the line of the previous cicatrix, the zygoma again chiselled off, the three branches of the nerve as it emerged from the foramen ovale was divided, and a section of the nerve nearly an inch long removed. Since then absolute freedom from pain and good motion of the jaw has resulted.

A similar case of recurring neuralgia after division at the dental foramen has been treated in the same way, the foramen ovale being plainly visible after the section and removal of the nerve.

Dr. Weir commended the procedure above any of the others resorted to for the relief of neuralgia of the fifth nerve, not only because of its access to each of the lower branches at its highest external point, but because of the ease of the operation itself and its freedom from subsequent impairment of the motion of the jaw. These advantages do not so satisfactorily belong to the methods of Horsley and others. As the point of recurrence is well brought out in these cases, it is possible that additional relief may be called for in the future. Then the external method of Rose to reach the Gasserian ganglion, which allows only of imperfect work, can be resorted to, or—more dangerous but more thorough—the skull can be opened and the ganglion reached and extirpated either preferably by Hartley's plan of keeping outside the lifted-up dura mater, or by employing that of Horsley, who opens the dura and exposes the ganglion by raising the brain itself from the cranial base. This is confessedly the more dangerous procedure, and offers no advantage over Hartley's simpler method.

DR. MCBURNEY said he was rather of opinion the internal operation suggested by Dr. Hartley was not a very dangerous one.

DR. WEIR had intended to say merely that it was more dangerous than the other alluded to.

DR. MCBURNEY doubted even that. The healing was

very rapid, and as the dura mater was not opened he did not see that any special danger was incurred. The simple act of opening the skull would not, in the light of numerous recent trephining operations, seem to increase the danger. He was at present accustomed to treating all trephine operations by immediate suture, without drainage. The internal operation, without opening the dura, offered a very clear view of the parts to be removed very near their origin, and he hoped and believed that it would prove safe and satisfactory.

The President asked Dr. McBurney whether any trophic disturbances had followed the operation.

Dr. McBurney replied that he had seen none, but the cases were too recent to speak definitely on that point.

Dr. Weir said there were two cases on record in which damage to the Gasserian ganglion had been followed by loss of the eye, but when asked by Dr. A. H. Smith whether that was not the usual result of experiments on animals, he replied that it had not been true of the three or four operations upon man.

The President thought the explanation suggested by one gentleman, that the destruction of the eye might have resulted from want of protection to the cornea, was not correct, for injury to the trigeminus might pass without eye lesion, while pathological destruction of the Gasserian ganglion had caused inflammation of the cornea and atrophic disturbances.

Dr. Andrew H. Smith remarked that in the experiments upon animals to which he had referred, destruction of the eye took place within two days after removal of the Gasserian ganglion.

Dr. Beverley Robinson raised the question whether—since previously to the operation done by Dr. Weir upon this patient the more formidable procedures resorted to had been followed by a return of the symptoms—it would not have been safer and better to have given him such relief as could be afforded by rational medication.

Dr. Weir replied that he accepted the view which had been expressed by Dr. McBurney, that not all these operations were formidable ones. They were safe procedures, and although they might be followed by recurrence, yet the patient had a period of absolute freedom from the pain which was very gratifying.

Dr. McBurney also expressed the opinion that the operations done upon the patient presented were quite justified, for they were not formidable, and often resulted in complete respite from pain as long even as three years. It was only after failure of such procedures that anything like a formidable operation was resorted to. He had never seen any serious accident result.

Microscopic Specimens from Trichiniasis.—Dr. Andrew H. Smith presented under the microscope one of the mother-worms found in the vermiform appendix of a patient who had died of trichiniasis.

Note on the Use of Heart Stimulants, and Particularly of Strychnine, in the Treatment of Acute Lobar Pneumonia.—Dr. J. West Roosevelt read the paper (see p. 728).

Dr Beverley Robinson expressed some surprise that strychnine could be given in such large doses without producing toxic phenomena, for in some patients much smaller doses had seemed to do harm by interfering with sleep and causing irritability.

It had been more or less common in New York, for a year or two, to employ in pneumonia a pill composed of aconitin, strychnine, and digitalin. Considerable doses of digitalin, repeated every hour, or two or three hours, during the twenty-four, had been taken by some healthy adults without any appreciable effect upon the pulse or respiration, and Dr. Robinson had begun to think that there was a good deal of difference in the action of certain of the alkaloids, especially between those of the crystalline and those of the amorphous form, the latter being much less efficient. He doubted whether digitalin given in the pill already mentioned was a heart stimulant of great value.

Withhold Stimulants until they are Needed.—Dr. George L. Peabody thought the author's experience very valuable, and that it ought to be tested by others. He fully agreed with him with regard to the impropriety of giving stimulants, especially alcohol, to a patient because his heart might become enfeebled, but was not yet so. He could not believe that such was a general practice, unless by medical tyros. He had frequently to curtail the amount of alcoholic stimulants prescribed by the house staff in hospitals.

Dr. Andrew H. Smith had been much surprised at the amount of strychnine which Dr. Roosevelt had been able to give. Such experience illustrated the fact that many powerful drugs could be given in much larger doses than had been supposed. For example, who without experience would not be startled at the amount of arsenic given by Dr. Osler, especially in pernicious anæmia: half a drachm of Fowler's solution three times a day. In giving alkaloids it should be borne in mind that they did not, as far as he knew, add anything to the nutrition of the heart-fibre. Their action was simply that of applying the whip, which might be useful in carrying the patient over a critical period, as it would in urging a horse over a weak bridge before it could collapse. If the stimulants were used long, forcing the heart into unnatural activity, it was at the expense of molecular action and loss of strength, and was liable to bring on bankruptcy. Digitalis had never given him much satisfaction in pneumonia except when the heart was becoming intermittent, when it might restore the rhythm. There was a distinction to be made between failure of the heart as a whole and failure of the right side of the heart. Right heart failure, as distinguished from heart failure, was liable to take place when there was much obstruction to the circulation in the lungs, and ought to be managed differently from the cases in which the primary danger was to the heart as a whole. For instance, raising the patient with pneumonia, in bed, incurred risk to the entire heart, because of its participation with the rest of the muscles in the general weakness induced by the disease. That was very different from the inefficiency of the right heart due to sluggishness of the pulmonary circulation.

Dr. F. P. Kinnicutt had given very large doses of strychnine hypodermically in pneumonia, with very satisfactory results. He had not, however, carried it up to one-thirtieth of a grain. If compelled to rely upon only one drug as a cardiac stimulant in pneumonia, he would choose strychnine. The uncertainty of some of the alkaloids had forced itself upon his mind, as it had upon Dr. Robinson's. He had used a certain preparation of aconitin in pneumonia with satisfactory results in obtaining the object for which it was given, the reduction of the pulse. The fall in the pulse, however, was sometimes alarming. Not infrequently the number of beats fell from ninety to forty. Response to alcoholic stimulants was likely to take place readily afterward.

Dr. Roosevelt said, during some concluding remarks, that tolerance for strychnine was quite easily established in pneumonia. He had seen no toxic symptoms or restlessness produced by it.

Report of the Fourth Laparotomy in a Hysteric Patient.—Dr. Joseph D. Bryant read the paper (vide page 726.)

Dr. Andrew H. Smith said that about January, 1892, a patient was brought to the Presbyterian Hospital who was vomiting fecal matter. She had a cicatrix in her abdomen, the result of a former laparotomy for the cure of a supposed fistulous connection between the colon and stomach. At first she was allowed to go to the closet, but subsequently this was prohibited, yet she vomited fecal matter as before. Then she was watched very carefully, and was on one occasion surprised with a handkerchief full of fecal matter concealed in the bed, ready to be swallowed. Immediately after this discovery she asked to be discharged, and he supposed she went pretty straight to Bellevue.

Pretended to Vomit Blood.—Dr. Peabody said that, some years ago, when he went on service at the New York Hospital, he was told by the physician who preceded him that there was a woman in the ward who vomited large quantities of blood, and that she must have an ulcer of the stomach. The amount of blood vomited was so great that all were surprised she did not become exsanguinated and die. The newspaper reporters were writing up the case of the charming young actress who was dying of some obscure disease at the hospital. On two or three occasions a large basin half full of the blood was sent to him at his laboratory for examination, and he found that it looked like fresh blood, but it did not coagulate. She was placed under surveillance, and was found to have one pretty constant visitor who dressed like a countryman, was old enough to be her father, and who wore a duster which screened a package of some size. He ordered this visitor to be excluded, whereupon the vomiting of blood ceased. Then on examination her trunk and wardrobe were found to contain a number of large bottles in which the blood had evidently been brought by this visitor, obtained, it was thought, at some slaughter-house, defibrinated. After this exposure and some others she left the hospital, but was brought back several times by ambulance. He afterward heard that she was in a house of prostitution. Dr. Tuttle, who was then senior house-physician, said the thermometer registered 110° to 112° F., except when held by the physician, and then it recorded normal temperature. It was not discovered how she caused the rise.

Dr. Norris, present by invitation, said he saw Dr. Bryant's patient in the hospital ward of the Penitentiary, where he performed the third laparotomy referred to in the paper. She had been in the Penitentiary three months when she began to have apparently fecal vomiting. The house-surgeon saw her vomit next day, and in the afternoon laparotomy was performed, but they found no intestinal obstruction, or connection between the stomach and intestine. After a time the fecal vomiting began again, she refused to eat, and wished to be fed by the rectum, but there was no vomiting of the fluid injected. She was discovered by the nurse leaving her bed and taking food from other patients. He believed she was still seemingly vomiting fecal matter when she left the hospital.

The President suggested that had this patient been put through all the tests for hysteria, concentric limitation of the field of vision and other evidences of that state might have been found.

A New Drug with Specific Action on Lupus.—The discovery of the eclectic action of *Thiosinamine* upon diseased tissue by Dr. Hebra has awakened very great interest on account of the value that the new remedy apparently possesses in the treatment of lupus, caries, necrosis, and other inflammatory processes. Thiosinamine is prepared from the volatile oil of mustard by heating a mixture of two parts of the oil, one part of absolute alcohol, and seven parts of liquor ammonia, sp. gr. .960, in a waterbath at 40° C. for several hours. In the trial cases which Hebra undertook two to three divisions of a Pravaz syringe, equivalent to five to seven grains thiosinamine, were injected twice weekly. With these small quantities a visible improvement in the disease was apparent, although in lupus of not very extensive character the reaction was often so slight as scarcely to be observed. In the case of inflammatory affections of the eyes it was sufficient, however, to considerably increase the inflammation, the intensity of the reaction being in inverse proportion to the extent of the process. With lupus patients the dose was increased in the third week to half a syringeful, and in the fourth and fifth weeks to a whole syringeful, of the fifteen per cent. solution, the latter dose being continued for two or three months, so long as the typical reaction occurred and the cure was not completed.—*Notes on New Remedies.*

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE SEATS OF HÆMOLYSIS AND THE NATURE OF THE HÆMOLYTIC CHANGE—THE ACTION OF CHOLAGOGUES—SUCCESSFUL EXCISION OF CANCEROUS GROWTH OF ILEUM—ATHLETIC EXERCISES AS A CAUSE OF DISEASES OF THE HEART AND ARTERIES.

London, December 3, 1892.

In his second lecture, Dr. William Hunter proceeded to discuss the question as to what were the seats of hæmolysis. The organ which at once suggested itself, he said, was the liver; the spleen was also, at least, a probable seat of the process. Observers, however, were by no means agreed as to the significance we should attach to the blood-pigment so frequently found in one or other of these organs, or in the bone-marrow. It was still an open question how far the presence of pigment in an organ indicated that that organ was the seat of an actual destruction of blood-corpuscles, as distinguished from a mere burial-place of old corpuscles that had gradually become functionless. It also remained to be ascertained—assuming that these organs were the seat of hæmolysis—to what extent they acted independently or in association with each other, and how far their relative activity in this respect might be judged of by the relative amount of blood-pigment they contained.

Dr. Hunter said his observations on the spleen lent no support whatever to the view that the presence of blood-pigment was in any way connected with, or could possibly be referred to, the occurrence of capillary extravasations of blood. So far as mere collecting function was concerned, he found the liver a far more important organ than the spleen, as judged by the results of injecting carmine or ultramarine blue into the blood. He found experimentally that the cells of the spleen had the power of arresting red corpuscles before the latter had undergone sufficient change to allow of their enclosure by leucocytes He concluded that the spleen was the most active organ in the body in withdrawing from the blood red blood-corpuscles in process of becoming effete, and that its activity in this respect was greater than that of the whole body of leucocytes. Evidence of a similar, though less conclusive, character was afforded by experiments on the bone-marrow. In regard to the liver, his observations lent no support whatever to the view that a destruction of blood took place within the liver-cells; whatever hæmolytic change occurred in the liver took place within the capillaries. Presence of blood pigment within the capillaries had, therefore, a certain significance. Blood-pigment within the cells afforded no index whatever of the amount of hæmolysis that had taken place in the liver; it was only evidence that so much hæmoglobin had been broken up within the liver-cells, without affording any indication as to where the preceding hæmolysis had occurred—whether in the capillaries of the liver, or outside the liver, or in the spleen, or in the circulation generally.

The lecturer remarked that the information derivable from a study of the distribution of blood-pigments as to the seats of hæmolysis, was comparatively limited, and mainly negative in character. He had derived more important information from a study of the morphological changes found in plasma, red corpuscles, and white corpuscles during active hæmolysis. He had injected poisons—and especially toluylenediamin—into the blood to induce active hæmolysis. He found that the spleen was the chief seat of active hæmolysis. The rôle of the liver was subordinate. Toluylenediamin frequently caused a largely increased deposition of blood-pigment within the liver—especially within the cells. It was, however, evident that the liver had little to do with the destruction thus caused, since, by removing the spleen, the destruc-

tion could be abolished altogether. The sole part the liver took in the process was to dispose of the products, especially of hæmoglobin. After removal of the spleen where did hæmolysis occur? As regarded blood-pigment, the place of the spleen was taken chiefly by the capillaries of the liver and by the bone-marrow, but blood-pigment had but a limited significance in this relation. He had found experimentally that the chief seat of hæmolysis after removal of the spleen was not the liver, but the portal capillaries within the gastro-intestinal tract. This area was second only in importance to the spleen.

Hæmolysis being thus confined mainly to the capillaries within the portal area, all the products must pass through the liver before reaching the general circulation. It was then the rôle of the liver became manifest. A certain amount of blood destruction might take place within its extensive capillary area, but the chief rôle of the liver was, not to induce hæmolysis, but to dispose of its various products, whether chemical or morphological.

Important differences existed between the hæmolytic action of toluylenediamin and substances like pyrogallic acid, glycerine, or distilled water. The latter acted directly on the blood, the amount of destruction being proportional to the quantity injected, and ceasing when they had left the blood. The action of toluylenediamin, on the other hand, was not immediate but more remote, and took place at a time when not more than a few milligrammes were to be found in the whole blood. Nor was it proportioned to the amount injected, for it might be great with a small dose (when the spleen was present) and absent altogether with double the dose (when the spleen was absent). Outside the body its addition to normal saline solution, in proportions as great as one-fourth, one-half, or one per cent., actually increased the preserving power of such a solution toward red corpuscles, while within the body it gave rise to the most marked changes in the red corpuscles. Further confirmation of this distinction was obtained from experiments in which the spleen was excised, and pyrogallic acid subsequently injected; the removal of the spleen did not materially influence the action of the latter. The lecturer regarded this result as establishing, (1) the important differences between substances that acted directly and those that acted indirectly in destroying the blood, and, (2) the importance of the spleen in determining the action of the latter. The importance of this consisted in the fact that, according to his observations, hæmolysis in health, and usually in disease, was of this indirect character. In disease the exceptions to this statement were paroxysmal hæmoglobinuria, and the hæmoglobinuria attending severe burns and scalds, where the destruction was obviously occasioned by direct action on the blood, and on the blood of the general, as distinguished from the portal, circulation.

Hæmolysis, then, in health was a process initiated by the activity of cells—more especially of those having a peculiarly close relation to the blood, viz., of spleen and gastro-intestinal tract. The degree of hæmolysis was strictly defined by the activity of those cells; it was therefore slight during starvation and greatest during digestion. The evidences of this change in the blood at this time were, (1) the increase of flow of bile and bile-pigments which occurred during active digestion, and, (2) the presence of many morphological changes in plasma and red corpuscles within the spleen, which, according to his observations, were to be found in such great abundance in the spleen during digestion, while comparatively few in number in the spleen of the starving animal. The activity of the cells of spleen and gastro-intestinal tract was also evidenced by the increase in the number of the luecocytes of the blood during digestion, and by the accompanying increased excretion of uric acid; also by the increased tendency of the portal blood to coagulate at this period.

Dr. Hunter concluded the lecture with a few remarks on cholagogues. Within the limits of health, he said, next to digestion, the greatest hæmolysis took place under the action of cholagogue agents. Their action was evidenced chiefly by an increased flow of bile and an increased formation of bile-pigments. The latter must have been preceded by an increased destruction of blood. Since, however, he had shown that destruction of blood occurred chiefly outside the liver, and was effected mainly by the lymphoid cells of spleen and gastro-intestinal mucosa, he concluded that the initial action of such agents was not on the liver, but on those other cells, and that the part the liver played was to excrete the products so formed. This view by no means excluded the one that these agents also influenced the activity of the liver-cells; on the contrary, such was probably the case. What he concluded, however, was that this action on the liver cells did not account for everything; it did not account for the chief change, viz., the preceding hæmolysis; but, to be effective at all, the cholagogues must first act on the blood through the intermediation of the lymphoid cells of spleen and gastro intestinal mucosa.

At the last meeting of the Clinical Society Mr. Arthur Roper read the notes of the case of a patient, aged fifty-four, from whom a cancerous growth of the ileum had been successfully excised by Mr. W. A. Lane and himself. A Keith tube was tied into the bowel above the stricture, through which the contents of the bowel escaped freely; the growth was excised a few days later. When the patient had gained strength and flesh, the question of establishing intestinal continuity and closing the abdomina wound was discussed, but the patient refused, as she was more comfortable than she had been for years.

At the Medical Society Dr. Collier, of Oxford, read a paper on "Athletic Exercises as a Cause of Diseases of the Heart and Arteries." He urged that the evidence was conclusive as to the effect of frequently repeated muscular exertion in the production ot heart disease. The danger lay in the frequent repetition of severe muscular effort. The lesions developed soonest in the badly fed. Dr. Collier referred to the researches of the late Dr. Peacock on Cornish miners, of Dr. Clifford Allbutt at Leeds, of Dr. DaCosta on the production of "irritable heart" in soldiers, and to those of Dr. Morgan on the after-history of university oarsmen. The latter physician had contended that the majority were benefited rather than otherwise by their exertions, but his researches bere upon picked and carefully trained men.

Bureau of Hygiene and Sanitation of the World's Columbian Exposition.—The above bureau has been organized under the Department of Liberal Arts, to prepare a collective exhibit illustrative of the present condition of sanitary science. The bureau will arrange for the presentation by exhibitors of models of sanitarily built and equipped dwelling-houses, urban, and rural, farm-houses, school-houses, public lavatories, closets, and urinals, crematories for the dead, crematories for garbage, etc. Laboratories for bacteriological research and for analytical investigations will be exhibited, food and food adulterations, the problems of water supply, drainage, sewerage, ventilation, and heating. The following is the general classification under the division of Hygiene: Gymnasia and gymnastic apparatus, alimentation, dwellings, etc., hotels and lodging-houses, public baths and lavatories—a group which seems to include, in the circular of the bureau, everything from urinals and earth-closets to wall-paper, clothing, crematories, and laboratories; hygiene of the workshop and factory; protective supervision.

Some Cruel Things for Anti-vivisectionists to Look after.—Castrating horses, pigs, sheep, dogs, cats, etc.; docking horses' tails; hunting foxes, hares, rabbits; hooking fish for sport; shooting pigeons at matches; poisoning rats with strychnine and arsenic; fattening geese for *pâte de foie gras*; trapping rabbits.

OUR BERLIN LETTER.

ERYTHROMELALGIE—A NEW DISEASE—LOUISE LATEAU RELAPSE—THE RESULT OF EXTIRPATION OF KIDNEYS FOR THE RELIEF OF TUMORS OF SAME—THE EXTIRPATION OF 135 C.C. OF GANGRENOUS SMALL INTESTINE—THE ETIOLOGY OF PERTUSSIS—PROFESSOR V. PETTENKOFER'S EXPERIMENTS AND IDEAS IN REGARD TO THE CHOLERA —PROFESSOR LEYDEN ON THE CHOLERA BACILLI.

BERLIN, November 22, 1892.

SINCE the abatement of the cholera medical matters are drifting in different directions. As medicine stands to-day, there is hardly a single disease that has not undergone a bacteriological crisis, and it will seem quite a sensation to state that diagnosis of disease with the aid of plate-cultures and éprouvettes seems to have been discarded for the older approved methods, which are clinical only, and which have stood the test for so many centuries.

That we can find numerous interesting points without the aid of the bacteriologist, seems to have been shown by a paper read in the last meeting of the Berlin Medical Society, by Professor Senator, on "Erythromelalgie." The disease is not entirely new; it was first mentioned by your distinguished countryman Weir Mitchell. It was, however, almost forgotten until recently Gerhardt, Senator, and Bernhardt simultaneously rediscovered it.

The disease affects men in middle age, say thirty to forty-five years of age, more especially those exposed to tedious journeys. At the commencement there are severe neuralgic pains, localized usually on the lower, seldom on the upper, extremities, redness of the affected parts, increased temperature, and sometimes swelling. Heat increases the severity of the symptoms. The disease assumes a decidedly intermittent character, and disappears in winter. The course and duration of the disease are as yet unknown. Anatomically, the redness can be defined as an erythema, but it is somewhat different in the erythromelalgie. A similarity has also been traced with the erythema exudativum multiforme.

According to the author, he bel eves it to be an angioneurosis, due to paralysis of the vaso-constrictors, and possibly an irritability of the vaso-dilators. The prognosis is uncertain, for up to date no deaths are on record. A rational therapeusis does not exist as yet. In the case mentioned here, Senator used the constant current and faradic electricity, as he believed, with decided success.

A modern Louisa Lateau was presented at this same meeting by Dr. Schimelbusch, assistant in Professor v. Bergmann's clinic. The patient, twenty-five years of age, had a large ulceration on her left mamma, the size of a plate; the origin seemed to be due to pricking the skin with a pin. The border of the sore showed new blisters, which interfered with the healing process. Transplantation of skin was unsuccessful. She was then strictly watched in v. Bergmann's clinic, and there was applied a tight-fitting plaster jacket on the thorax and arm. Transplantation now proved successful, although fungous granulations would not yield to the consecutive application of caustic nitrate. Besides, these blisters seemed to come on the neck, thorax, and arm. Only after gauze was made fast to the skin by means of photoxylin did the parts heal thoroughly.

According to the opinion of this surgeon, he believed it was a case of "hysterical self-injury," whose object consisted in being interesting to physicians. The clinical picture reminds one of the stigmata of the Catholic wonders in healing, especially, however, on the symptoms of the renowned case of Louisa Lateau, which created such a sensation in 1874.

Especial interest has been centred in the remarks of Dr. James Israel, one of Berlin's most prominent surgeons, in regard to kidney extirpation for the relief of malignant tumors affecting the same. Until now, the operative mortality for the relief of the above malady was about fifty-three to sixty-one per cent., so that for this reason the operation was laid aside. Israel, however, has performed this operation in the last few years 54 times. Of these 11 proved to be malignant tumors, and of the latter 2 died (or eighteen per cent.) as a result of the operation. Of the surviving ones 2 died, one after six, the second after thirteen, months of metastatic abscess. In the oldest cases, of which one is now five years and six months old (after operation), the result has been a cure.

This surgeon based his success on the early diagnosis of the tumors in question, which was by means of a careful palpation easily mapped out. In one case Israel was able to detect a tumor of the size of a cherry in a kidney which he presented, in which, on the inner half of the kidney, was a tumor of the size of a silver dollar, which was so well developed that although existing a short time, it had grown into the albuginea.

In the succeeding meeting of the Berlin Medical Society there followed a paper by Dr. Schlange, assistant of Professor v. Bergmann, on "Resection of Small Intestine (gangrenous)." This patient was admitted with symptoms of ileus, a high, convulsive, swollen abdomen, with distinctly palpable intestinal folds in the umbilical region. Diagnosis wass trangulation in ileus, next prompt laparotomy. A large black-colored piece of gut (small intestine) presented, with the mesenterium strangulated close to the vertebral column. After loosening the strangulation a portion of intestine, with its mesenterium extending a length of 135 c.c., was removed, owing to gangrene. The patient rallied from this heroic procedure and was discharged cured recently. This is probably one of the largest resections on record.

In the same meeting Dr. Ritter, one of our young bacteriologists, spoke of the etiology of pertussis. This speaker found that the disease was not localized in the upper portion of the larynx, but in the lower portion of the air-passages. He therefore proceeded to examine the bronchial secretions. He proceeded to obtain the secretion by receiving that which is thrown out by emesis at the end of the coughing spasm, and receiving it in one of his test-tubes. The sputum was then carefully worked with distilled water according to the recent (new) method of Koch, and from the resulting mass small flocculent pieces picked out for careful determination. After careful washing with a flow of water, this lentil-shaped piece of secretion was planted on sterile agar. After twenty-four hours colonies of diplococcus were found, which this investigator believes to be the cause of the pertussis. This diplococcus grows on agar of different compositions (*i.e.*, dextrose, plain agar), but does not grow on gelatine, potatoes, nor bouillon.

On the surface of the agar these colonies grow in a chain-like manner, seeming to run one into another, and have a grayish color, and can be easily removed.

This diplococcus is aërobic, and temperature optimum lies between 36° to 38° C. Below 30° and above 42° nothing grows. It stains very readily with basic and aniline dyes. In form, as also in biological relations, this diplococcus differs from all others, especially from the pneumococcus (Fränkel). The quantity of the bacilli seems to be in ratio to the intensity of the disease. The animal experiments are not all completed yet, but this investigator inflated the pure culture into cats and dogs, and produced attacks which were quite characteristic of pertussis.

Quite a sensation was created by Professor v. Pettenkofer in a recent announcement at the Munich Medical Society. His comments were on the question whether Koch's comma bacillus was really the cause of cholera or not. In order, therefore, to prove this, Professor Pettenkofer, and after him Professor Emmerich, introduced virulent cultures of cholera bacilli into their stomachs after having weakened the gastric secretions. Both gentlemen got along well without any harm after their experiment. This proved to Pettenkofer that the comma

bacillus does not produce the poison necessary for a cholera infection by its presence in the intestine. Pettenkofer then went into the history of previous epidemics, and found that the transmission of cholera could not be suitably traced to the existence of the comma bacillus. Then going to the Hamburg epidemic, which he characterized as explosive in character, he compared it to an epidemic in Munich. He decidedly disapproved of the drinking-water theories in regard to cholera. It had been universally accepted, but he knew of epidemics where drinking-water had never been thought of, and was not the source.

He insisted on statements made by him in 1885, at the Berlin Cholera Conference. He did not dispute the etiological importance of the comma bacillus, but believed that certain other factors were necessary to produce an attack of cholera. Finally, Pettenkofer mentioned certain precautions in the prophylaxis of cholera, and criticised them. It was first tried to prove the existence of a case of cholera, isolate it, disinfect thoroughly, and then believe that the locality was safe. This is false, for it is impossible to check the distribution and spreading of cholera bacilli. The best method would be the abandonment of the dwelling-places and their destruction. It is useless to prohibit travel, and it is only in those localities where an epidemic positively exists that congregation of the masses and marketings should be prohibited. That Germany tried to avoid intercourse from a contagious stand-point has proven an expensive experiment. The fear of the cholera bacilli is wrong, intercourse in houses where cholera exists is not dangerous.

Whatever may be said of the foregoing, which is contrary to the established doctrine of Koch, it is a decided scientific sacrifice on the part of this aged scientist to try such a serious experiment on himself.

These auto intoxications of these Munich scientists do not prove much, for numerous people are decidedly immune against cholera infection, or better, cholera intoxication. Here, as in numerous other cases, we are brought in contact with the relationship which the bacillus bears against the vital energies of the subjects, and about which we know nothing. It is, however, worth mentioning that Pettenkofer's ideas have numerons sympathizers in Berlin, especially in independent medical circles.

So, for example, might be mentioned the remarks of Professor Leyden, at the Society for Internal Medicine. He said that he accepted Pettenkofer's views, and stated that the representatives of bacteriological ways in medicine were entirely too dogmatic in their views. He said too much weight was laid on bacteriological methods, and clinical methods were put in the background. The same was true in regard to the prophylaxis in the late cholera epidemic. It was decided to neutralize and kill, if possible, the cholera bacillus in the patient, and try to prevent spreading of the disease by combating the bacillus within, and also without, the patient afflicted. In this many rights, which should otherwise have been bestowed, were taken away from the patient.

He finally reminded those present about his views, after the tubercle bacillus was discovered in 1882, when so much was mentioned in regard to the dangers of the tuberculosis, when he advised and warned against accepting all new views and theories as facts.

In each case the self infection of Pettenkofer and Emmerich will open a new era in the question of cholera which may bring considerable fruit from a hygienic standpoint.

Nostrums at the World's Fair.—Rule 15 of the pamphlet on Classification and Rules issued by the World's Columbian Exposition reads as follows: "Articles that are in any way dangerous or offensive, also patent medicines, nostrums, and empirical preparations whose ingredients are concealed, will not be admitted to the Exposition."

OUR CANADIAN LETTER.

(From our Special Correspondent.)

MEDICAL COUNCIL OF ONTARIO—RECIPROCITY IN MEDICAL REGISTRATION—TORONTO UNIVERSITY AND QUEEN'S UNIVERSITY MEDICAL DEPARTMENTS—A FREE JOURNAL—QUARANTINE PRECAUTIONS—AMALGAMATION OF CANADIAN AND AMERICAN MEDICAL ASSOCIATIONS—PERCENTAGE OF MEDICAL MEN TO INHABITANTS OF ONTARIO.

The Medical Council of Ontario has, during the past year, been subjected to a great deal of sharp criticism, and evidently the end is not yet. The object of the Council at its formation was no doubt merely to act as a licensing body, before which all graduates in medicine, after paying a fee of one hundred dollars, must appear for examination before receiving legal qualification to practise in the province of Ontario. A few years ago, however, some members of the Council conceived the idea of erecting an expensive building in the city of Toronto, where real estate at the present time is, on account of the untimely collapse of a boom, exceedingly flat. The building is a most elaborate structure and has many adornments, the most prominent one of which is a decoration in the form of a mortgage for an amount many consider more than the property could now be sold for. To meet this financial stringency the Council has received legal permission to levy an annual tax of two dollars on each medical practitioner in the province of Ontario, with authority to remove the name of any delinquent from the medical register who fails to make a prompt remittance before December 31st in each year. The result has been the formation of a strong association to protest against the extravagance of the Medical Council. There is little doubt that at the coming meeting of the Provincial Legislature a strong effort will be made to have some sweeping changes made in the Ontario Medical Act, and one of these changes will certainly be to have the Medical Council more largely composed of representatives elected by the medical practitioners of the province, instead of having it, as it now is, largely controlled by the university and college men. At present each university and each medical college in Ontario has a representative at the Medical Council. Many of the members are gentlemen having the best interests of the profession at heart, but unfortunately the machine element too largely prevails. No one denies the fact that the Medical Council of Ontario has done a great work for the profession in the province, and many regret most keenly that through financial matters so much sharp criticism has been provoked.

Nearly every province in the Dominion of Canada has now its own medical council, but it seems a peculiar anomaly that the license to practise in one province is not recognized in another. The question of reciprocity of medical registration between the provinces has excited a good deal of discussion, but so far no definite action has been taken in the matter. A medical practitioner of high repute, and a professor in a medical college in one of the older provinces, removed a few months ago to one of the western provinces of the Dominion, and wishing to engage in practice went before the board of examiners to procure registration. He found on that board one who had formerly been a student under his tuition in the East, and who did not hesitate by catch questions to expose the weak places in the applicant's knowledge of anatomy; and so successful was he that the former professor retired from the presence of the board chagrined with the announcement that he would have to try again. Medical registration is certainly looked after most carefully in Canada, and each province seems to be jealous of the other in carefully guarding its rights. There is danger, however, of carrying the matter too far.

The recent election to the Senate of Toronto University has occasioned among many of the medical graduates a most bitter feeling, that at the present time threatens to

impair the usefulness of the Medical Department of Toronto University. The cause lies largely in the undue ambition of a junior clique, whose efforts to remove from the faculty some of its most honored members have happily proved of no avail. There has also been an effort made to introduce the political machine, and work it for the advancement of those whom it seemed calculated to help. All these dissensions are greatly condemned, particularly by members of the profession in the Province, without whose support in the way of encouraging the attendance of students the Medical Department of Toronto University could not be maintained. Influencing students to shun an institution where such discord prevails would mean the shutting off of supplies. Several are now trying their hands as peacemakers, but with what result remains as yet to be seen.

The Royal College of Physicians and Surgeons of Kingston will hereafter be known as the Medical Department of Queen's University. This is one of the oldest medical institutions in Canada, and its many friends will wish it a long continued measure of prosperity in the new relation it will hereafter sustain to a university so well endowed as Queen's.

The Medical Council of Ontario, recognizing the fact that the imposition of an annual fee on all medical practitioners in Ontario was exceedingly unpopular, has entered into a contract with a Toronto publishing company to supply free to each medical practitioner in the province a monthly medical periodical, known as the *Ontario Medical Journal*. In consideration of an annual bonus of six hundred dollars paid by the Medical Council, each of the twenty-four hundred medical men of Ontario now receives every month a copy of the new journal, which is at least equal in literary merit to any other medical publication in Canada. It naturally commands a large advertising patronage, and on this account is said to pay its promoters handsomely. The proprietors of other medical journals naturally complain, as this innovation is likely to seriously interfere with their subscription lists.

The Canadian Government has demonstrated its anxiety to leave nothing undone in perfecting the quarantine regulations, and taking other precautions to prevent the entrance of cholera into the Dominion. The provincial boards of health have the confidence of both the profession and the general public. Expecting that the St. Lawrence route will be largely patronized during the coming year by visitors from Europe going to the World's Fair, extra efforts are now being made so that nothing will be left undone that would be likely to prevent the entrance of cholera to Canada. There was certainly the greatest need for reform, especially in the quarantine equipment of the lower St. Lawrence.

At the late meeting of the Canadian Medical Association at Ottawa many expressions were heard favorable to the proposed union of the American and Canadian National Associations. It will be remembered that at the meeting in Detroit, in June last, Dr. Reed, of Cincinnati, gave notice of a resolution to come up for discussion at the meeting in Milwaukee next year, in favor of the amalgamation of the American with the Canadian Medical Association, and thus establish a Continental Medical Association. Such a scheme has long been spoken of by the medical profession in Canada. No action has, however, been taken, it having been wisely considered best to await the action of the American Medical Association in the matter, and accordingly no public discussion on the subject took place at the recent meeting. The Canadian Medical Association, now in its twenty-sixth year, has accomplished a great deal of highly useful work that has proved scientifically beneficial to the profession in Canada. The feeling, however, has lately been gaining ground that a union, such as has been proposed, might be consummated with mutual advantage to the whole profession in America. Sir James Grant, at the meeting of the Canadian Association in Montreal last year, made an eloquent address strongly advocating the federation of the two associations, with annual meetings at which the medical profession of United States and Canada might meet for scientific investigation and discussion. Although thoroughly British in his political sentiments, Sir James, as one of the leading members of the profession in Canada, has wisely concluded that political divisions must never prove a barrier to the most harmonious union of those forces which have for their object the promotion of the scientific welfare of medicine. The cities of Montreal and Toronto would be glad to welcome the meeting of the united associations, and many Canadians hope that the action of the American Medical Association in the matter will be favorable to an early and harmonious union of the two associations.

There are now twenty-four hundred legally qualified medical practitioners in the province of Ontario, which, according to the last census, would give one medical man to every nine hundred of inhabitants.

THE STERILIZATION OF CATGUT.

To the Editor of the Medical Record.

Sir: In reading Dr. Dowd's article in the issue of December 3d, upon "An Apparatus for the Sterilization of Catgut," it has occurred to me that it may be of benefit to some surgeon who should desire to prepare catgut by boiling in alcohol, and did not possess the necessary condenser, to be informed of a plan of condensing which I have used in the New York Cancer Hospital, with most gratifying results as regards the sterility of the gut. The gut is wound raw upon a large spool (about two inches diameter, and four or five inches in length), the spool to be solid so as to sink. The size of the spool I mention as important, from the fact that you get sufficient length wound without causing the layers to be more than three, or at the most four, deep. This spool is immersed in absolute alcohol, and the jar containing it set upright in the hot water (which should at least be on a level with the alcohol); a good sized piece of ice is then placed upon the top of jar, and as the alcohol vaporizes, it rises to the cool top, is condensed, and falls back into the jar. After boiling for thirty minutes the jar is removed, the cover securely fastened, and kept for use. I have never seen bad results arise from gut prepared thus, and have prepared as heavy as No. 8, which was used in tying the stumps in oöphorectomies.

Yours truly,

Jay O. Nelson, M.D.

3501 Wabash Avenue, Chicago, Ill.

THE LOCALIZATION OF THE ACTION OF REMEDIES UPON THE BRAIN BY INTRA-NASAL MEDICATION AND COMPRESSION OF THE INTERNAL JUGULAR VEINS.

By J. LEONARD CORNING, A.M., M.D., Etc.,

NEW YORK.

In the light of what has been and is still being accomplished by the topical use of chemicals in the treatment of the most diverse morbid conditions, I fancy that few will deny that the judicious extension of the principle is an object worthy of one's efforts.

To enumerate what has been done in this field would involve nothing less than a recapitulation of all that has been achieved by local antisepsis, local anæsthesia and the topical use of remedies in the various medical specialties. Thoughts of these things are freighted with suggestions, of a practical kind too, let me add, or I should not have recalled them. When one considers to what meagre practical results some of the fashionable generalizations of recent pathology have conducted us; and when over against this poverty of achievements one places what has been attained by the localization of the effects of medicinal substances, I believe the most sceptical therapeutist will not only acknowledge, but gladly acknowledge, how substantial have been our acquisitions. It may as well be admitted, however, at the very threshold of these reflections, that the concentration of the effects of chemical solutions upon the internal organs is beset with difficulties, insurmountable ones too, in many instances. Thus one reads in the journals from time to time accounts of injections of medicinal fluids into the parenchyma of the lung, or other important viscus, but the thought at once occurs that these fluids can at best produce but evanescent effects upon neighboring morbid products; for they—the fluids—are soon carried away to distant parts of the organism by the circulation; and being thus dissipated, their local remedial effects are proportionately attenuated.

There is, however, one organ which is exceptionally well placed with respect to the possibility of concentrating the action of remedies upon it; I refer to the brain, and more especially the cortical layers of the cerebrum.

To appreciate how true this is, it is necessary to place in juxtaposition the following facts:

1. That the main blood-supply of the cortex is contingent, or largely contingent, upon the unobstructed flow through the carotid and jugular vessels. Hence, when the blood flow in one or both of these sets of vessels is arrested, or even partially arrested, as by compression, cortical function is directly interfered with, as is shown by the confusion of ideas, stupor, and even unconsciousness engendered.

2. It has long been known—and the fact has frequently been commented upon in medical literature—that chemicals applied, especially in a fluid state, to the lining membrane of the nasal cavity are speedily absorbed, producing in this way characteristic physiological effects. Thus calomel has been blown into the nose, producing in a short time severe salivation.[1] Narcotic substances, and more especially morphine and cocaine, have also been spread upon the mucous membrane of the nasal cavity, giving rise in a short time to characteristic phenomena. I am told that the effects thus induced upon the central nervous system, and more especially the brain, by the use of the last-named drug are familiar to rhinologists.

The most reasonable and generally accepted explanation of the prompt action of narcotic substances when used in this way is that which assumes that the absorption of the remedy—or at least the greater part of it—takes place by the way of the vessels which penetrate the lamina cribrosa. If we admit the plausibility of this hypothesis, we shall then perceive that remedies administered by way of the mucous membrane of the nose must reach the brain, and especially the cortex cerebri, in a more concentrated state than when administered at a distance, either hypodermically, per rectum, or by the stomach. Even though the amount of medicinal substance absorbed be not great, its increased concentration at the seat of influence (the brain) must of necessity result in physiological effects out of proportion to the quantity of chemical involved.

Here we have an explanation, and I think a true one, of the remarkable cerebral symptoms often produced by exceedingly small quantities of medicinal substances when applied in solution to the eye and conjunctiva.

3. It is a fact that, if narcotic fluids be introduced into the nasal cavity in the manner previously set forth, and if shortly thereafter the flow of blood in the jugular veins be considerably retarded by the application of pressure at a suitable point in the neck, the effects of the remedies thus administered may be appreciably enhanced and prolonged. This accords with all that I have been able to ascertain respecting the behavior of remedies when brought in contact with the peripheral nerves, by hypodermic injection, and maintained there by occlusion of the capillaries, or by constriction of the artery, veins, or both, above the point of injection (next the heart). These preliminary observations will, I trust, make the principles involved abundantly clear to any physician of average intelligence. Let me pass, then, at once, to the description of the simple procedure which I have found most serviceable in giving practical effect to the principles above enunciated. The first step of importance is the introduction of the remedy by way of the nose. To do this most effectually the mucous membrane should first be cleansed with warm water, the latter serving at the same time to expand the capillaries. The medicament (morphine, cocaine, atropine, etc.) may then be introduced in solution through the nostrils by the aid of an ordinary medicine dropper or atomizer. This simple manipulation is best accomplished while the patient reclines upon his back.

After the lapse of ten or fifteen minutes the second step may be proceeded with. This consists in materially restricting the lumen of the internal jugular veins by the application of pressure.

After numerous trials, I have found that the jugulars are best compressed by the application of small dry cups over the course of the vessels, one at each side of the neck on a level with—or a little below the level—of the thyroid cartilage.

The cups, which are joined together in front by an adjustable steel band, are about two inches long and half an inch wide; they are made of metal—silver or steel—and

[1] De l'Administration des Médicaments par l'intermédiaire de la Muqueuse des Fosses nasales; par Rainbert, Journal de Médecine de Chirurgie et de Pharmacologie, Bruxelles, 1867, vol. xlv., p. 17, seventh line from top of page.

are held in place by an elastic strap, which passes around the neck and is secured in place behind by the aid of a simple buckle (Fig. 1). The open side of the cup is, moreover, somewhat concave in an antero-posterior direction, which admits of elevating the veins and surrounding tissue more effectually In this way it is possible to draw the vessels into the cups, partially at least, thus causing the edges of the latter to act energetically upon the lumen of the veins. The little dry cups being maintained in position over the vessels by the aid of this simple band, the air contained in them is rapidly exhausted by means of an air-pump and vacuum-chamber, which exert their influence upon the interior of the cups through the intermediation of small, non-collapsable india-rubber tubes (Fig. 2).

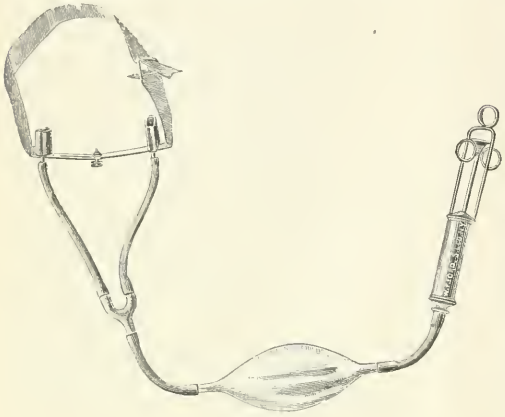

FIG. 1.

It is self-evident that the cohesion of the compressing apparatus thus obtained, as well as the elevation of the tissue within them, render valuable assistance by preventing the slightest displacement of the subjacent vessels. In a word, the veins, instead of being compressed in a backward direction, are, as previously pointed out, drawn toward and compressed by the edges of the cups. When all is properly adjusted, the elastic bands previously described may be tightened at will, thus adding mechanical to atmospheric pressure. This last step is usually, however, unnecessary, the atmospheric pressure being adequate.

When slight vertigo has been induced in this way, the evidence is conclusive that the stasis of the intracranial venous circulation is sufficient for therapeutic purposes.

There is no special limit to the length of time during which compression may be continued; but from what I have been able to determine, I should fancy that from twenty minutes to half or three-quarters of an hour are sufficient.

Illustrative Cases.—The following cases are cited with a view to illustrate the facility and rapidity with which a variety of disagreeable sensations in the head, including minor degrees of pain and depression, are relieved by resort to this simple procedure.

Mr. A. C—— was referred to me over three years ago by Dr. C. H. Avery, on account of "severe and persistent headache." When I first saw him the headache was diffuse in character, continuous, but not specially severe. He informed me, however, as I find by reference to my case-book, that at times he is afflicted by sudden and very severe exacerbations of pain; and that, at such times, the pain is almost entirely confined to the occipital region. There is very little difference between the pain felt at night and that experienced during the day.

There are no ataxic symptoms; the disks of both eyes are normal, but the pupils are quite uneven, the right one reacting little or not at all to strong light. I sent him to Dr. David Webster for an opinion, who wrote me that there was undoubted "paresis of the right sphincter iridis, without paresis of the ciliary muscle." A high degree of hypermetropia was also present, for which Dr. Webster prescribed the necessary glasses, to be worn constantly. Incidentally he also expressed the belief, in spite of the absence of a specific history, that the mydriasis, and probably also the headache, were due to nervous syphilis.

My own suspicions having taken a like direction, I placed him at once upon large doses of the iodide of potash, which were gradually increased to the point of tolerance.

After several weeks there was appreciable diminution of the pain, so much so that after three months his visits were discontinued. A year or two later I saw him again, and he stated that he was often free from pain for prolonged periods—from several days to three or four weeks.

The paresis of the right sphincter iridis was also apparently improved, though the contraction of the pupil was quite sluggish.

So far as my case-book reveals, I did not see him again till October 19, 1892, when he called at my office, complaining of an unusually severe paroxysm, the predominantly painful area being located in the frontal region. This seemed a good opportunity of testing the above method of locating the action of remedies upon the intracranial structures.

Accordingly I placed the patient upon his back, injected into both nostrils, as high up as possible, several drops of a medicated solution, aggregating morphine $\frac{1}{8}$ grain and atropine $\frac{1}{100}$. Ten minutes later, there being as yet little diminution of the pain, I compressed both jugular veins in the manner previously set forth.

FIG. 2.

The relief thus afforded excited the wonder of the patient, who declared, after the lapse of five minutes from the time of applying the compression to the jugulars, that he "felt no pain."

Later he informed me that the relief thus obtained was unusually prolonged, there being little or no pain exper-

ienced during the entire following week. I shall have something to say regarding the subsequent history of this interesting case, at some future time. My object in citing it on the present occasion is merely to show how promptly a relatively severe frontal headache was relieved by medication by the nose, combined with simultaneous compression of the internal jugulars.

Mrs. E. N. T—— was referred to me by Dr. Charles A. Limeburner for severe, continuous local headache, possibly the result of circumscribed chronic meningitis (?).

Five months ago, while walking in the garden, patient stepped upon the prongs of a rake, which had been allowed to remain in an upright position, so that the handle leant against a wall. The result of this action was to cause the implement to fly forward, inflicting a blow of such severity upon the left side of her head that she fell to the ground in a state of partial or total unconsciousness.

On regaining consciousness, she felt nothing more than the soreness which might naturally have been anticipated from the violence of the contusion. In a few days, however, quite severe pain set in, the painful sensations being deep-seated and corresponding quite accurately with the area of traumatism, *i e*, the left parietal region.

As the pain was not relieved by extracranial measures, and as the various coal-tar derivatives did not seem to help her much, or, at all events, but slowly, I decided to endeavor to act more directly upon the intracranial structures by invoking the method of medicinal localization previously described.

Accordingly, while the patient lay on her back, I sprayed into her nostrils morphine, gr. $\frac{1}{8}$; atropine, gr. $\frac{1}{250}$. Ten minutes thereafter, patient experiencing little relief, I applied the pneumatic compressor over the jugular veins, with the result that, within five or six minutes from the moment of its adjustment, there was complete cessation of pain. Here, again, we have conclusive proof of the increased physiological potency of medicinal solutions, when they (the solutions) are made to linger in the tissue of the brain or other portion of the central nervous system by the aid of artificially induced stasis or partial stasis in the capillaries. Such stasis may be induced in three ways—and I have tried them all—first, by compressing the carotids; secondly, by compressing the jugulars; and lastly, by compressing both the arteries and veins. Compression of the jugulars with the least possible interference with the circulation in the carotids, will alone be discussed on this occasion.

Compression of the jugulars by the aid of the pneumatic compressor, as here described, is not difficult, especially when the patient reclines in a dorsal position, the head being thrown slightly backward so as to place the vessels slightly on the stretch. This procedure may be invoked without hesitation in the treatment of individuals under forty years of age.

In elderly persons, on the contrary, where an atheromatous condition of the cerebral blood-vessels is among the possibilities, it will be well either to abandon this mode of treatment, or to compress both arteries (carotids) and veins (jugulars) at once, thus avoiding an increase in intra-arterial pressure and consequent danger of rupture and hemorhage.

Mr. V. N——, also kindly referred to me by Dr. Charles A. Limeburner, has suffered for several months from what Dr. Limeburner believes, and rightly, I think, to be neursathenic headache.

The chief complaint of this gentleman is that he is beset by a sensation of heaviness in the head, more or less continuous, and frequently coupled with dull pain at the vertex and profound depression. In addition to these symptoms, he also evinces dread of responsibility and society, loss of memory, especially for recent events, inability to concentrate his attention for any length of time without discomfort; and, in short, he affords a typical illustration of the classical form of cerebral neurasthenia.

With a view to at once gain his confidence by relieving his head symptoms—the vertical pain, the heaviness, and the depression—I proceeded to invoke once more the aid of medicinal localization.

Instilling into the nasal cavity a few drops of water containing atropine, $\frac{1}{100}$, and cocaine, gr. $\frac{1}{4}$, I applied the pneumatic compressor, as already so frequently described. After the lapse of five or six minutes there was a decided feeling of relief, and in ten or twelve minutes the disagreeable head symptoms had entirely disappeared. The relief in this case was complete during the following five or six days, when the procedure was again repeated, with the same results. As a matter of course, various measures directed to the removal of the exciting cause were employed in this as in all similar cases, but as they have no bearing on the point at issue, and involve, moreover, matters which are part of the common knowledge of the profession, I have made, and shall in future make, no detailed reference to them. As a matter of theoretic interest, I may observe that, after instillation of the atropine and application of compression to the jugulars, there was marked dilatation of the pupils.

Mr. J. E. K—— has been kindly referred to me by Dr. Fayette Smith, on account of an obstinate form of myalgia. He also suffers from attacks of mental hebetude, depression, and headache. During one of these seizures, which failed to yield to either salol and phenacetine, or antipyrine and ammonia, I instilled into his nostrils morphine, gr. $\frac{1}{8}$, atropine, gr. $\frac{1}{100}$, and hyoscine hydrobrom., gr. $\frac{1}{300}$, and shortly thereafter applied the pneumatic compressor to the jugulars.

As a result all the disagreeable symptoms disappeared within ten or fifteen minutes, much to the delight and astonishment of the patient, who had hitherto failed to obtain relief from several remedies administered in the conventional manner.

Mr. L. E—— has been referred to me by Dr. David Webster, on account of paralysis of the third nerve, with concomitant headache, both phenomena being doubtless specific in origin. Dr. Webster has already obtained some amelioration by the administration of the iodide of potash combined with inunctions of the oleate of mercury. As, however, there is still considerable diplopia, Dr. Webster feels that local applications of electricity should be tried. Accordingly, I have made such applications (of faradism) as near the vicinity of the affected muscles (left internal and inferior rectus) as possible, employing for the purpose a delicate conical sponge electrode.

The benefit accruing from this phase of treatment has been rapid, the double vision having quite disappeared after the third application. I may add, in this connection, that the eye was thoroughly cocainized before applying the electrode, the lids being held apart by an ordinary eye-speculum.

And this brings us to the point of special interest in connection with the present argument. As has already been said, this patient was a sufferer from headache of a persistent, dull character, culminating, at times, in exacerbations of considerable severity.

At my request he called at the office during one of these attacks, and I proceeded at once to attempt to abolish the painful symptoms. Spraying the nasal cavity with an aqueous solution of morphine, gr. $\frac{1}{8}$; cocaine, gr. $\frac{1}{3}$; and hyoscyaminæ sulphas, gr. $\frac{1}{100}$, I had the patient remain in a recumbent position for ten or fifteen minutes. At the end of this time, he stated that he felt "somewhat better;" but, as the relief was not complete, I at once applied the pneumatic compressor to the jugulars, when the patient almost immediately declared that all pain had vanished.

Mrs. C. L. V—— was referred to me by the late Dr. James R Leaming, on account of persistent insomnia, accompanied by attacks of dull, clawing pain at the vertex. As the patient was much debilitated, and as changes in position —and notably lying down and suddenly sitting up—had a perceptible effect upon the character of the pain, I concluded that circulatory anomalies, probably anæmia, had

something to do with its genesis. Accordingly, I applied the compressor to the jugulars, with the result that considerable relief was at once afforded. This improvement was, however, evanescent; for, on removal of the compressor, it shortly returned.

I then proceeded as in the previous case, instilling at first the analgesics and sedatives into the nasal cavity, and then applying the compression to the jugulars. Precisely the same results were obtained as in the previous case—relief from pain, lasting several hours.

This case is interesting, as it affords incontestable proof of the superiority of jugular compression combined with intranasal medication over jugular compression alone.

Mr. G. F—— was referred to me several years ago by the late Dr. Cornelius R. Agnew, on account of spinal neurasthenia, accompanied by impairment of sexual vigor and insomnia. For several years patient had been harassed by imperative craving for alcoholic stimulants, the morbid desire occurring periodically, twice or thrice yearly. The excesses which resulted from these impulses always left the patient tremulous and greatly prostrated, and eventually he became a victim of obstinate and constantly recurring headaches, in addition to the symptoms which had more especially attracted Dr. Agnew's attention. The eye conditions bore no special relation to the case, consisting as they did in a minor degree of hypermetropia and conjunctivitis. Appropriate glasses had corrected the first, and a simple eye-wash the second element, so that when he arrived at my office the nervous phenomena were the predominant, and indeed the only, feature. These I was able to abate by a course of treatment of reasonable length; but I was not able to overcome the patient's imperative impulses to periodic spreeing.

Thus it happened that, for the last few years, this gentleman has been in the habit of seeking me out, after one of these debauches, with a view to having the results—the head pains, the tremor, the depression—eliminated. Recently he called upon me for the usual purpose, suffering, as he declared, more than on former occasions. Especially annoying was the sensation of fulness and pain in the head, which made him feel, as he expressed it, "as though he would like to jump off the dock." This seemed a good opportunity to endeavor to relieve the pain by concentrating the effect of the remedies employed by the aid of jugular compression.

As the patient was a sufferer from an old catarrhal difficulty, which had evidently deprived the nasal mucous membrane of much of its absorbent power, I decided to administer the remedies by the mouth. I quite realized that in doing this, I was resorting to a method inferior to that previously described, when judged by rigid physiological standards; for these demand the placing of the medicament as near the nervous structure to be affected as possible. However, I could not help feeling that the retardation of the medicated blood in this way would eventuate in some enhancement of physiological effect, and the sequel proved that the inference was a correct one.

As a preliminary precaution, the patient was given forty drops of the aromatic spirits of ammonia, and shortly afterward fifteen grains of antipyrine were administered. Though the ammonia, being quickly absorbed, induced a considerable increase in the frequency and vehemence of the heart's action, there was no abatement in the head symptoms—the pain, hebetude, and depression—even after the lapse of half an hour. And yet there was some diaphoresis, showing that a considerable quantity of the antipyrine had been absorbed.

It was at this juncture that I applied the pneumatic compressor to the jugulars in the usual way.

The phenomena thereby evoked appeared within five minutes and were truly remarkable, if credence is to be given to the patient's own statements. He declared that the heavy feelings in the head had disappeared; that he no longer felt pain; that the depression had entirely relinquished its hold upon him; and that, in a word, he was "cured," as he laconically expressed it.

Commentary.—Obviously, the plan of treatment just described has distinct advantages; for, when the nasal mucous membrane is sufficiently healthy to absorb the medicament, the stomach, if delicate, may be spared the reception of chemical products which might add to the local derangement. Powerful alkaloids are those best adapted to this form of administration, as they may be given in small doses, and are, therefore, readily taken up by the nasal mucous membrane, whose power of absorption is limited. Again, there is little or no danger of setting up a pernicious habit, as is the case in hypodermic exhibition. Then, too, the prompt relief of intractable symptoms in a relatively short time, and without inordinate drugging, is a notable advantage. Finally, I would add that where the nasal mucous membrane is not sufficiently healthy to absorb the medicated fluid in sufficient quantity it may be injected into or beneath the intranasal mucous membrane by the aid of a long hypodermic needle attached to the syringe conventionally employed. This I have done on one occasion, only.

53 West Thirty-eighth Street.

HOW AMPUTATION OF THE BREAST FOR CARCINOMA SHOULD BE PERFORMED.[1]

By ROBERT F. WEIR, M.D.,

Professor of Surgery, College of Physicians and Surgeons, New York.

The subject upon which I wish to speak to-night is an extremely trite one, and I can add but little of novelty to it. Nevertheless I think the experience of every hospital surgeon will bear me out in this, that while the removal of the female breast for carcinoma is an operation that is frequently undertaken by the ordinary practitioner, in a large number of instances it is done in an imperfect manner. Either the operator will content himself with the removal of the tumor, together with a moderate portion of the adjacent mamma, or he may more thoroughly take away the entire breast with the tumor. He seldom, however, opens and examines the axilla, and still more rarely does he enucleate this space of its fat contents and glands, which are estimated to be invaded in ninety-seven per cent. of mammary carcinoma. This latter omission is especially true in those instances where, prior to the operation, no glandular enlargement can be detected, even after repeated and careful examinations. That this inference is erroneous has been demonstrated many times by surgeons. Experience has decisively shown that such an examination is not a reliable one; that even the opening up of the inferior portion of the axilla, after the breast has been removed, and the introduction of the finger under the skin into this space is not sufficient in many instances for the detection of involved glands. The discovery of enlarged glands in the axillary fat has been so frequently found by me in cases where no evidence of the existence of such could be felt prior to the operation that I speak with positiveness on this subject. In fact, according to the carefully observed cases of Schmidt, at Küster's clinic in Berlin, twenty-six per cent. of the cases not presenting, previous to operation, axillary involvement to the usual palpation revealed enlarged glands at the time of operation.

Passing on further, and as briefly as possible, as my time is limited by your President, the following may be stated almost as axioms:

First. That every mamma in which a cancerous nodule exists is already very extensively diseased—perhaps *in toto*.

Second. That secondary infections take place either through the axillary glands and lymphatics, or through the adjacent skin; or, lastly, through the retro-mammary fat and fascial tissues alone, or in addition through the lymph-vessels of the pectoral fascia and of the pectoralis major muscle itself.

[1] Read at the Meeting of the County Medical Society, held November 28, 1892.

From these facts it is equally evident that the whole breast must be removed, and that the section through the skin must be made wide of the growth, irrespective of the formation of a line of subsequent union; also, that the axillary contents should be thoroughly cleaned out; and finally, and perhaps most important, if the disease extends to the depths of the gland, that the pectoral fascia, and generally a portion of the pectoralis major muscle itself must also be removed.

The usual incision, starting on the arm at about the insertion of the pectoralis major muscle with the humerus, is carried along the lower edge of this muscle rather than in the axilla itself, and encircles the breast below and above the tumor. Dissection through the subcutaneous fat will now, by turning back the separated skin, easily expose the mamma *en masse*. These incisions, I repeat, should always be planned on the basis of going wide of the affected part. Unluckily we have no way of determining how far away this section should be, or how much of the skin tissue of the breast should be sacrificed. Two procedures have been suggested, one of which has been in use for some time, to aid the surgeon in this endeavor. The first is, by the aid of a competent assistant, to make at the time of the operation a frozen microscopic section of the diseased skin tissue nearest the carcinoma, in order that the operating surgeon might be informed before the close of his work whether or not he may have taken away a sufficient amount of the skin and other tissue. This has been resorted to for some time past by myself, as well as by other surgeons, and the delay in the operation has been so trifling that its advantages more than counterbalanced this defect.

The second method, which I can only allude to, for my own experience has been confined to but a few cases, is that suggested by Stiles, of Edinburgh, and it is this: To immerse the amputated breast, previously washed in water in order to remove the blood, in a five per cent. watery solution of nitric acid, and to leave it there until the operation of cleaning out the axilla has been accomplished, say ten minutes. It is then washed again in water. By this time such alterations will have taken place from the action of the nitric acid on the normal tissues as will render them semi-translucent, while the carcinomatous patches will remain opaque. This ready method has been endorsed by Professor Chiene and by Messrs. Woodhead and Brooks.[1] Moreover, since we have learned that the large gaps, particularly such as are frequently left after the free removal of the mamma, and which are often so extensive that the edges of the skin cannot be joined again together, can be satisfactorily and promptly closed by Thiersch's method of skin-grafting from the thigh, there need be no hesitation on the part of the surgeon to sacrifice more of the skin than has heretofore been done. This is an important point, because it is admitted by all that the recurrences are most common, viz., seventy per cent., in the skin and in the tissues near the site of the original infection. It is for the further avoidance of this recurrence, for in the axilla recurrence is rare—less than two per cent.—that, in addition to the liberal removal of skin, Heidenhain, of Berlin, has proposed that always in the deep involvement of the mamma, or when the retromammary fat or tissue is invaded by the neoplasm, not only these tissues should be widely removed, but that a goodly portion of the pectoralis major muscle itself in the mammary region—in his own words, "a continuous layer of the muscle substance"—should be cut away. This I can testify can be done to an extensive degree, either without after-impairment in most cases, or, in rare instances, with extremely slight impairment of the function of the arm. In one case I recently removed nearly the entire pectoralis major muscle, and subsequently the patient only felt some very moderate inability to press the opposite deltoid region as firmly as before.

So far all is plain sailing, even for a beginner in surgery. The entire breast, and its probably subjacent affected tissue, has been freely removed, let us say. The hemorrhage resulting is easily checked by clamps, which can be left on till the rest of the operation is completed, and by this means alone all bleeding will probably be controlled. If not, torsion will generally accomplish the end aimed at, and only rarely will a ligature be required. The clearing out of the axilla, which next should be done, is not a difficult procedure either, providing certain rules that are now commonly followed by surgeons are employed, the principal one of which is that the axillary vein should be exposed at the beginning of this procedure. This bugbear to the young surgeon is easily overcome, thanks to Bickersteth's and Volkmann's directions. These are in substance as follows: After the original incision through the skin and subcutaneous fat previously described (which can, however, be altered in the mammary portion according to the various situations of the carcinomatous growth) has been made along the line of the pectoral muscle and the diseased breast properly removed, there will be seen, just below the lower border of this muscle, in the axilla, a thin layer of fascia which is readily recognized (Fig. 1). This

FIG. 1.—Axillary Fascia.

axillary fascia can be further exposed, if necessary, by a moderate dissection along the posterior edge of the incision up to the latissimus muscle. A few touches with the knife will now set plainly into view nearly the full width of the axilla, hemmed in by this layer of fascia, which stretches from above the vessels and is adherent anteriorly to the whole external border of the pectoralis major muscle. The position of the artery underneath it is not seen, but it is readily felt, and below this point an opening is made in the fascia either by a touch of the knife or by tearing through it with the end of a blunt pair of scissors, whereupon it can be divided through a distance of two or three inches up to the pectoral border. The fat beneath gently being torn through with the finger, or the end of the scissors, will immediately reveal the blue, large, axillary vein. This having been cleared of the loosely adhering fat, though sometimes adhering glands complicate the manœuvre, the anterior attachment of the fascia along the pectoral muscle is then divided throughout, from above downward, and the fat of this space, working from the vein downward and outward, is, as a rule, readily dissected out from this cavity. Usually a few small veins and several thoracic nerves will traverse the mass of fat, and these are generally sacrificed. The intercostal humeral nerve, also stretching across the same, generally demands its severance, though, as in some cases where but slight glandular involvement is met with, this can be spared. Following in this way along the chest-wall, one comes, proceeding backward, down to the

[1] Medical News, October 31, 1891; British Medical Journal, May 7 and 14, 1892.

subscapular muscle and to the subscapular vein as it runs into the exposed axillary vein. Here will be found, adjacent to this vein and running from above downward and outward, the subscapular artery, and, what is of great importance to us, as shown by Küster, of Berlin,[1] the second subscapular nerve (Fig. 2). This, it is very desirable, should be spared from injury, for it and the third subscapular nerve, not often seen in these operations, and lying more to the outside, supply the teres major and latissimus dorsi muscles. Its incautious severance is a common cause of the subsequent inability to raise the arm after these operations. It is easy to avoid damaging it, when once on the lookout for it.

In this way the axillary fat, sparing this nerve, can be enucleated from the subscapular muscle up to the edge of the latissimus dorsi muscle, where a few snips of the scissors or cuts with the knife will sever the axillary fat from its posterior and outer attachments in such a manner that it can be removed *en masse* with the fat tissue of the previously detached breast. Individually, however, I prefer to remove the breast completely as the first step of the operation, and then to take out the axillary fat. After the removal of the fat and gland

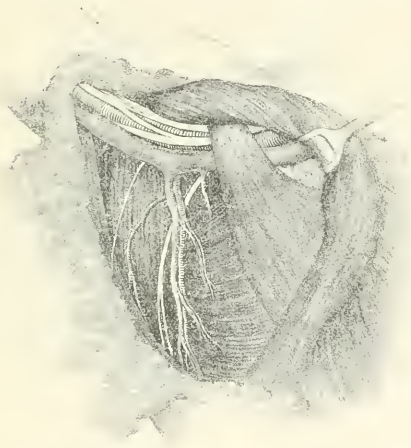

FIG. 2.—Showing the Second and Third Subscapular Nerves, with the axillary contents turned outward, and also the exposure of Mohrenheim's subclavicular space. The axillary artery and nerves are not bared however during a mammary amputation.

from the axilla there will be left quite a pocket, at or near the bottom of which, and posteriorly, it is wisest to make a drainage opening.

Should an involvement of the vein wall be discovered one should not hesitate to sacrifice the vessel by removing the diseased portion after ligating above and below the affected part. Should, by any mishap, the rare accident of damaging the otherwise healthy vein take place, it is best closed, if a very small opening, by a lateral ligature; if an opening of any size exists, its closure is best effected by several interrupted silk sutures.

To lend further security to the clearing out of the axilla, an expedient which I have employed now for many years, should, in my judgment, be always resorted to. It is, to explore higher up in the axilla that space called by the Germans Mohrenheim's, represented also in Fig. 2, and situated just below the clavicle. This is accomplished by separating with the fingers the cellular plane between the pectoralis major and pectoralis minor muscles, until the clavicle is felt, and then by flexing the arm somewhat upon the chest the pectoralis major muscle itself is lifted up by the fingers of an assistant or by a retractor. By so doing, this space, containing the axillary vessels and a small amount of fat, is readily exposed to view and to palpation. In it will often be found, if enlarged glands have been met with in the axillary fat, one or more small-sized carcinomatously involved glands. With the fingers, and sometimes the end of a curved blunt scissors, not by cutting, this fat can be entirely removed. If any difficulty in so doing occurs, the finger passed underneath the pectoralis minor muscle will crowd this fat sufficiently forward to bring it entirely within the control of the surgeon. I venture to repeat that this is a region the exploration of which I have for a long time insisted upon as being of great importance. Its investigation has not usually been dwelt upon, but I cannot but feel that its systematic examination will lend additional security to the patient. The separation of the two pectoral muscles likewise often reveals a diseased lymph-vessel running alongside the cephalic vein.

The drainage-tube, preferably a glass one, is carried in through the skin opening, either under or above the pectoralis minor muscle, and the wound then closed throughout by a few silk-worm-gut sutures, to which is added multiple sutures of the finest silk. Occasionally iodoform gauze is substituted for the drainage-tube—for drainage-tubes do not drain long, as they soon get choked up and the exit of the wound secretion is generally, after a few hours, only accomplished by the space outside the drain. Careful pressure of the replaced flaps of skin, if they come together, is made by wet or dry aseptic towels, or otherwise, during the suturing. The accumulation of blood and the formation of a blood-clot is not encouraged. The customary antiseptic dressing is applied and secured by broad canton flannel bandages, and finally fixation of the arm and forearm is carried out as thoroughly as possible.

An operation thus conducted, though much larger than is usually planned, is singularly free from mortality. Of one hundred and twenty-five primary operations conducted in this manner I have not had a single death. In seventy cases operated upon by the older methods I have had two deaths, one from thrombosis of a damaged axillary vein, and the other from erysipelas. Dennis, in seventy-one cases, had but one death. Schmidt's later cases showed but two per cent. of mortality. As to the effect of such or similar thoroughness as this upon the ultimate results the figures presented are encouraging. Twenty per cent. of the cases operated on are reported by Schmidt as cured; twenty-five per cent. of similar cures are given by Dennis. My own data give me in sixty traced cases nearly twenty per cent. of cures. By this is meant that no recurrence has taken place within three years from the date of the operation, a generally received indication of a permanent successful result though not an absolute one. The very late recurrences, such as are occasionally met with, which I have seen, for example, in one instance, taking place sixteen years after the operation, in another case twenty years after the operation, are to my mind more likely to be explained in view of the increasing probability of the protozoal origin of cancer by a reinfection than by a recurrence of the primary disease.

Centralblatt f. Chirurgie.

An Optimist at Last.—In the last number of the *North American Review*, Dr. T. D. Crothers discusses the question, "Is alcoholism increasing among American women?" He decides that inebriety among women is on the decrease. The great majority of cases of drunkenness in females are seen in connection with profound physical and mental degeneration. Female drunkards are "the mere wreckage of worn-out foreign families far down on the road to race extinction. . . . Drunkenness, prostitution, and lawlessness of all forms in women are unmistakable signs of disease and early dissolution. Only a small minority of American women are found at this level. On the street at nightfall, in large cities and low circles, a certain number of inebriate women may be seen; but these are largely demented beings of foreign birth, paupers in mind and body."

THE TREATMENT OF ULCERS BY STRAPPING.

By CHARLES E. QUIMBY, M.D.,
NEW YORK.

JUST one hundred years ago a good surgeon of Bristol, England, Baynton by name, gained more lasting glory than falls to the lot of most medical men by describing a new method of treating ulcers by the use of adhesive straps. After the lapse of a century it seems permissible, without evincing disrespect for things ancient, to suggest that his method, although to-day given without essential modification by all surgical authorities, may possibly be improved upon. In extenuation of my own digression from work essentially medical I can only plead an inherited love of all things mechanical and an early surgical training.

Fourteen years ago, on entering a surgical service in Bellevue Hospital, I received the honor, with a pride many will appreciate, of having placed under my sole care the usual goodly number of old stock ulcers, after due instruction in established methods of strapping.

For many weeks these same old sores received more faithful attention than often falls to the lot of such cases. As time wore on, however, while the ulcers mostly failed to wear off, neither youthful enthusiasm nor a reasonable sense of duty sufficed to gild them with the rosy hues of earlier days. An attempt to make practical the results of some self questioning as to what indications were being fulfilled was met with such stern reproof from an omnipotent "House" that further experiments were postponed until they could be conducted under the mantle of authority. The method then developed from an application of mechanical principles to the recognized indications I have practised and taught to my private students for the past thirteen years.

However valuable or generally available in hospital service recent methods of skin-grafting may be, the chronic ulcer has not yet become a thing solely of historical interest. That it may be cured in most instances in a small fraction of the time required under the common methods of strapping or bandaging I know. I therefore take the liberty of recalling the indications for the use of adhesive straps and pointing out the necessary method of their application to most completely fulfil these indications.

Adhesive straps can fulfil these indications:

1. Approximation of ulcer margins: Thus diminishing the cavity to be filled by granulation, the surface to be covered by cicatrization and the subsequent injury from contraction. Such approximation implies the production of more or less cutaneous tension, and unless such tension is uniform circulation and local nutrition will be impeded. It is impossible to produce even moderately uniform cutaneous tension by the old method of strapping.

2. Compression: Either for absorption of inflammatory exudate and new tissue, or to restrain exuberant and prevent fungoid granulations. Such compression also must be uniform and elastic.

3. Support of tissues: Thus favoring circulation and nutrition.

4. Relief of tension and bending in cutaneous border of ulcer. The most important indication, as bearing on local nutrition and the one which common methods of strapping most completely fail to fulfil.

To attain in the most satisfactory manner and degree the foregoing indications the following method of strapping will be found competent:

1. Adhesive straps should not be over one inch in width, and usually a narrower strap is to be preferred.

2. Straps should be as short as is consistent with a firm hold on healthy skin, and should never fully encircle the limb.

3. All straps should be applied at *right angles* to the long axis of the ulcer, subject to slight modification by the direction of greatest cutaneous elasticity, and are to be adjusted in two sets.

First set.

4. These straps are applied in the usual manner by fixing one end on healthy skin and approximating the edges of the ulcer as the other end is applied and fixed.

5. The first strap of this set should *bisect the ulcerated surface.*

6. Each succeeding strap of this set should bisect uncovered ulcerated surfaces.

7. As any strap becomes loosened one end should be freed and reapplied under appropriate tension.

8. Straps should be applied in this manner until the uncovered strips of ulcerated surface are narrower than the straps in use. The second set is then applied.

Second set.

9. Each strap of this set is to be applied from its centre to both ends simultaneously under appropriate tension, so as to cover an exposed strip of ulcer, and overlap two adjacent straps of the first set. To accomplish this, the straps are held by both ends and adjusted while being firmly stretched.

The degree of tension under which these straps are applied will depend upon the tension under which the first set have been adjusted. If applied under too high tension they will cause puckering of the straps of the first set.

When it is desired to have the tissue compression especially even, it is well so to arrange the first set of straps that the strips of ulcer to be covered by the second set are reduced in width to a narrow line. Even when this is done it is quite as well to use at least a half-inch strap for the second set. When the strapping is completed openings for drainage may be made as necessary.

The essential factors in the foregoing method are:

1. The straps are all applied in the same direction, that of the desired traction, and therefore render their full adhesive value.

2. No two straps are allowed to come in contact until the second set is applied. As the major part of the effect depends upon the first set of straps this principle of noncontact is of the utmost value. As succeeding straps relieve the strain upon those already adjusted, any loosened strap can be detached and reapplied without disturbing others, and thus each strap made to exert its equable portion of tension and compression.

3. To gain the most even results, this condition of equal strain should be maintained from the outset of the strapping rather than attempted after all the straps of the first set are applied.

The results which can be obtained by careful and intelligent use of the above method are so far superior to those by any other measures as to leave little if anything to be desired.

Simultaneous Epithelioma of the Lip and of the Penis.—In *The Lancet* a case of this kind is recorded by Dr. Turner. A man, aged twenty-four, with no family history of malignant disease and a negative result from syphilitic treatment presented himself with a harelip and a warty mass of four months' growth on his lower lip. Both were operated upon, the latter being shown by microscopical examination to be distinctly epitheliomatous in character. He now confessed to a similar growth on the penis, dating back nearly a year, which had been treated ineffectually by caustics. The growth formed a sore, large and ragged, with hard and somewhat everted edges, chiefly on the dorsum and nearly surrounding the whole penis, extending from within half an inch of the root to the same distance from the tip. The growth was removed, involving a very considerable portion of the penile coverings, but neither the corpora cavernosa nor the corpus spongiosum was invaded. The patient made a good recovery. In concluding, the author adverts to the rarity of the development of epithelioma in two places so remote from one another as the lip and penis, particularly in so young a subject.

Progress of Medical Science.

Congenital Inguinal Hernia in Females.—Dr. Paul Berger alludes to the following points as symptomatic of the congenital origin of inguinal herniæ in females, consequent to the complete closure of Nuck's canal: 1. The existence of smooth fibres of muscles in the hernial sac, representing a continuous layer, corresponding to the tissue of dartos. 2. The great abundance of vessels in the sac, continuous with those passing out of the inguinal canal and following the round ligament. 3. The existence of incomplete septa that pass into the cavity of the hernial sac in the shape of diaphragms, semilunar folds, or valves. 4. The existence of a complete septum separating the peripheral portion as a closed cyst. 5. Finally, and especially, the very solid connection of the thin serous wall of the sac with the round ligament which the sac accompanies, as the vaginal process of peritoneum does the spermatic cord in the male.—*Brooklyn Medical Journal.*

The Radical Treatment of Congenital Inguinal Hernia in Females.—According to Dr. Lucas Championnière, the palliative treatment by means of trusses is becoming somewhat restricted. Increased frequency of operating has extended our knowledge of the pathological anatomy of the less frequent kinds of hernia, and our views concerning the stative frequency of the same are changed. Thus congenital inguinal hernia in females appears to be by far more frequent than was heretofore generally supposed. Among fourteen radically operated inguinal herniæ in women, he found in ten instances conditions pointing to a congenital origin of the disease. Among the symptoms to be so interpreted in this connection he mentions the existence of the round ligament in the wall of a hernial sac, which is hollowed out as by a furrow; the solid attachment of the serous covering with this ligament; the occurrence of small cysts on the base of the hernial sac. In the radical operation Dr. Championnière recommends that the incision be made as high as possible, in order to remove the latter as great a distance from the vulva as possible. The operator invades the inguinal canal, seeks the hernial sac from above downward, rather than *vice versa*. The serous cover of the round ligament is so intimately adherent to the sac that the removal of the sac without taking along the ligament is impossible. Therefore he separates, as a rule, the ligament together with the sac as high up as possible, and after ligating removes it. He found no disadvantages arising from this resection of round ligament, the stump of resection again attaching itself to the abdominal wall. The author recommends, after separating the hernial sac and before tying of the same, examination of the uterine annexa through the incision; if found to be diseased, these are to be extirpated at once. He believes this examination to be necessary, as these organs, in case of inguinal herniæ, are frequently dislocated to the affected side and are often diseased. The author provides against recurrences by splitting, in every instance, the inguinal canal in its whole length, separating and removing the peritoneum as high up as possible, and then uniting solidly and accurately the extensive denuded surfaces with each other by means of numerous deep sutures. A truss is but rarely prescribed. The author's results are very favorable, the operation in each instance was invariably followed by recovery. A number of patients examined afterward were found to be free from recurrence; in the majority of the cases operated upon the time which has elapsed since the operation is too short to base a conclusion upon.—*Annals of Surgery.*

The Use of Sulphur Baths.—Dr. Barthélemy points out the value of sulphur baths, if properly employed. But he admits that they have definite limitations, and should be closely watched. In general, they should never be used in acute inflammatory diseases, or the acute stage of chronic affections. The best results are obtained in the torpid or terminal periods of chronic disorders of the skin, and their tonic action in such diseases as rheumatism, tabes, neuralgias, etc., is also very useful. All details should be carefully attended to, as these baths are rarely used as they should be. Three a week is a sufficient number, and not more than twenty-five minutes at a *séance*, the temperature being from 34° to 36° C., and maintained there by additional warm solutions at proper intervals. After careful study, a water resembling that of Barège was chosen, made by the use of precipitated sulphur, alkaline carbonates, chlorides, and silicates. The quantity should vary with the age of the patient, the texture of the skin, and the condition of the lesion. Great care should be taken not to irritate the skin and increase the trouble by the use of too strong baths.—*Le Progrès Médical.*

Amœbic Dysentery.—The clinical term dysentery includes various forms of intestinal flux due to inflammation, and usually ulceration, of the large intestine. While the primary etiological agents in the acute catarrhal and the diphtheritic forms of dysentery are as yet but imperfently understood, the so-called tropical variety of dysentery has been made the subject of investigations that show it to be a distinct disease from an etiological, a clinical, as well as an anatomical standpoint. The investigations of Losch, in Russia, of Kartulis, in Egypt, of Councilman and Lafleur as well as others in this country and elsewhere, show the amœba coli (Losch) of dysentery (Councilman and Lafleur) to be constantly present in the evacuations and in the intestinal lesions of tropical dysentery, as well as in the quite frequent secondary liver abscesses, and in the sputum after the rupture of such purulent collections into the lung. Kartulis and Hlava have made successful injections into the large intestine of cats and dogs with pure amœbic cultures on straw infusion or with dysenteric stools. The amœba is a unicellular, nucleated, protoplasmic and vacuolated organism, capable of amœboid movements, showing usually a clear outer zone or ectosare, and a granular and vacuolated inner zone or endosare; it varies in diameter from 10 to 30 or more micro-millimetres, and is very easily demonstrated in the warm stools of tropical or amœbic dysentery, the diagnosis of which practically rests upon the detection of the amœba in the discharges. The excellent clinical and anatomical studies of Councilman and Lafleur, based upon a thorough review of the literature and the analysis of fifteen cases of the disease, occurring mostly in Osler's wards, showed that amœbic dysentery has a variable onset, course, and duration, with intermissions and exacerbations, tending always to chronicity and early anæmia; that abscess of the liver with or without lung involvement is a frequent complication; that anatomically the ulcers differ from those of other forms of dysentery, being produced by a primary submucous infiltration and subsequent necrosis of the mucous membrane, and consequently they present very distinctly undermined edges; in these ulcers as well as in the liver abscesses purulent inflammation is absent unless a secondary infection with bacteria should occur. As is well known, tropical dysentery is very common in tropical and subtropical countries, where it frequently occurs in epidemics; but it also appears throughout Europe and North America. Musser has demonstrated the disease in Philadelphia, and Hektoen not long ago exhibited before the Chicago Medical Society specimens of the intestine with microscopical preparations, from a typical case occurring in a young man who died in Chicago, after having contracted the disease in Galveston, Tex. Comparison of the specimens of dysenteric intestine in the Army Medical Museum at Washington, gathered during the War of the Rebellion by the industrious and able Woodward, with the intestine of the amœbic dysentery of to-day, shows the lesions to be in many instances exactly alike. The natural habitat of the amœba dysenteræ has not yet been found, but it is thought that drinking-water is one of the sources of infection.—*Journal of the American Medical Association.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, December 31, 1892.

IS ERGOT USELESS IN OBSTETRIC PRACTICE?

MOST of the standard works on obstetrics contain passages recommending the use of ergot in certain conditions of uterine atony or inertia. And the administration of a dose of ergot after the completion of normal labor is a matter of routine with a large majority of practitioners. Dr. J. F. Baldwin vigorously opposes the practice, and combats the idea of the utility of ergot. In a paper published in the *Columbus Medical Journal*, October, 1892, he tries to show that ergot may be entirely dispensed with in obstetric practice. He says that the use of ergot may be considered under two heads: First, as a means of increasing uterine contractions for expelling the child, and secondly as a means to prevent post-partum hemorrhage. He adduces the testimony of various authors in regard to its dangers in assisting delivery. In the Rotunda Hospital, in Dublin, the use of ergot as an oxytocic before delivery has been prohibited by the present master. Playfair would limit its use to cases in which the first stage is over, and the os fully dilated, and when the experience of former labors has proved the pelvis to be of ample size, and when the perineum is soft and dilatable.

So fatal is the effect of ergot on the child, that Dr. Hosack says that while in some of the books, from its effect in hastening labor, it has been called the *pulvis ad partum*, in regard to the child it should be denominated the *pulvis ad mortem*.

Lusk is quoted as follow: "We should abstain from the use of ergot during the second stage, unless it seem necessary as a prophylactic against post-partum hemorrhage, and even under these circumstances it should never be administered if there is the slightest mechanical obstacle to delivery."

Barnes says: "Before whipping up the uterus to increased exertion, we must be satisfied that there is no obstacle in front so great that reasonable increase of driving force will not overcome without injury. We must be sure that there is no marked rigidity along the parturient track, no distortion or contraction of the pelvis, no disproportion or malposition of the fœtus, or other obstructive complication. The postulate is not always easy to obtain; and error or miscalculation may entail serious, even fatal, consequences. This is one objection to ergot. There are many others. The case, once entrusted to ergot, is likely to be beyond our control. We have evoked a brutal power like that given to Frankenstein. Ergotism, like strychnism, will run its course. If it act too long or too violently, you cannot help it. You may try epichontocics, as chloral, nitrite of amyl, or physostigma, but these may fail. The ergotic contraction of the uterus, when characteristically developed, resembles tetanus. Then woe to the mother if any obstacle should delay the passage of the child. And woe to the child if it be not quickly born. The ergotic contraction does not observe the physiological character of alternating diastole, systole, and repose—conditions necessary to the orderly circulation of the blood through the uterus, placenta, and fœtus."

Other opinions are adduced in support of Dr. Baldwin's rejection of ergot. He is willing, however, to admit that, if a preparation of ergot could be secured that would be at all times thoroughly reliable, and if personal idiosyncrasies in regard to its use were not so common, it is probable that a dose could be found of the drug which would simply serve as an adjuvant to increase uterine contraction, which should not go beyond the danger line; but unfortunately the reverse of all this is true.

For the last ten years he has not given a single dose of the drug, and he no longer carries it with him. He concludes by saying that ergot should be banished utterly from the lying-in chamber.

There doubtless has been, and to some extent there still is, too much of mere routine in the employment of this potent remedy. But we are not prepared to go as far as Dr. Baldwin and entirely discard so valuable a drug. It is true that it should never be used in a hap-hazard way, and that the indications for its employment should be rigidly formulated. But the same might be said of almost every drug of decided power in the whole pharmacopœia.

NYSTAGMUS AMONG COLLIERS.

THE most important work upon the subject of nystagmus, so says the *Bulletin de l'Académie royale de Médecine de Belgique*, 1892, is Romiée's "Study of Nystagmus among Colliers." This book represents years of patient research among thousands of miners afflicted with nystagmus, visits to numerous mines, relations with physicians who treat miners exclusively, and studies undertaken in common with these medical men. While not exhausting the subject, the brochure is a most valuable contribution to medical literature.

According to Romiée, the nystagmus of colliers is due to the excessive fatigue of the muscle of accommodation, that is caused by working in a dim light and in cramped positions unfavorable to clear vision. This excessive fatigue of accommodation induces clonic contractions of the eyeball, and brings about an occupation nystagmus in from twenty to sixty-five per cent. of all miners in whom the symptom has been sought for. The condition is painless and gradually disappears with change of work. It is not influenced, nor is it produced, by anæmia. It occurs generally in persons who have more or less hypermetropia. In the morning, on Sundays and holidays, the nystagmus is lessened.

But how, physiologically, can nystagmus be related to

fatigue of accommodation? Artl thinks it is established in the interest of sight. Owing to defective lighting in a shaft where miners work, retinal images are feeble and confused, in spite of instinctive efforts toward better accommodation. Nystagmus comes in to render clearer the visual perception of objects. It is a well-known fact that when sight is blurred, objects become clearer if kept in motion before the eyes. The collier, unable to keep in motion the objects that the eye fixes, moves the eyeball instinctively with such rapidity that the point of retinal fixation is brought back many times in succession in front of the same luminous point before the preceding impression is effaced, and each time receives a new excitation. In this way is augmented the intensity of the visual impression. The movement of the eyeball is involuntary and instinctive, and is simply a compensation. To this view Barcella does not incline. The nystagmus of colliers he looks upon as a functional disorder of the equilibrium of the eye muscles, a chorea. Dransart considers colliers' nystagmus to be a myopathy of the muscles that raise the eye (internal and superior recti, and the inferior oblique), that is intimately connected with anæmia and paresis of accommodation. This view is based upon the study of twenty-eight cases. In colliers the line of vision is always above the plane of the horizon. Hence overwork, fatigue, and paresis of the levator muscles.

SHOULD DOCTORS MARRY?

North Carolina is being agitated over the question whether the doctor should marry. A misogynic gentleman, Dr. Oscar McMullen, seems to think he should not. This blow at the rights and opportunities of woman is tempered with the statement that the doctor does not wish to "take one gem from the jewelled crown of pure and beauteous womanhood." He belongs to "that majority who believe that, of all the beneficent gifts from the creative hand of God, a woman, pure and good, excels them all, and is more beautiful than 'any other form of matter ever seen on land or sea, in flower or gem or living thing.'"

> "'As flowers beneath May's footstep waken,
> As stars from night's loose hair are shaken,'

so the most vivid joys which perfect the life of man spring wherever her gentle step is heard, and from her presence there is distilled the rarest benedictions upon the responsive heart."

Yet despite this glowing tribute Dr. McMullen thinks that lovely woman is the cause of many professional failures, and that she should be taken very cautiously. A loving and angelic wife may, he thinks, be a trifle exacting; and the cherubic infant sometimes produces insomnia, mental unrest, and a condition generally not suited to serious study and work.

We fear that the doctor is to some extent right. The wife of a physician has always a good deal to disturb her ideals both of household economy, domestic comfort, and connubial companionship. It requires some patience and devotion to accept all the irregularities and preoccupation of her husband's life with equanimity. There has to be some compromise, or friction results, and then work is difficult. However, it does not do much good to philosophize, for young doctors fall in love like other mortals, and then reason and experience count for but little.

News of the Week.

Middleton Goldsmith Lecture.—Dr. William P. Northrup has been invited by the trustees to deliver the above lecture before the New York Pathological Society in April next; subject to be later announced.

A New Hospital in San Francisco.—The French Benevolent Society of San Francisco is about to erect a hospital at a cost of $200,000.

A New Substitute for Cocaine.—The acetamide of eugenol—which is contained in oil of cloves—has recently been prepared; it occurs in crystalline form, and appears to enjoy the property of producing local anæsthesia in a very high degree. It may be used similarly to cocaine for this purpose, and, as it has no caustic action and is an energetic antiseptic, it may be found to be even superior to cocaine for minor operations on the mucous membranes.

A Conference on Cholera was held at St. Petersburg, December 13th. The purpose of the conference was to decide on the measures to be adopted to meet the fresh outbreak of the disease that is fully expected to occur next year, more particular attention being paid to the special measures demanded by varying local conditions.

Enthusiasm over any Particular Form of Treatment for Cholera must be tempered by the fact that in no place visited epidemically by the disease was the mortality-rate much less than fifty per cent. In certain parts of Poland it rose as high as ninety per cent. When the rate gets above fifty, something is wrong with the treatment or the people. When the rate gets below forty, the therapeusis is worth looking into.

Death of Dr. B. A. Watson.—Dr. Bervah A. Watson, of Jersey City, died at his home on December 22d, aged fifty-six years. Dr. Watson was a surgeon of prominence in the army during the war. Since then he has attained distinction in the profession by his medical works. Dr. Watson had not long ago made a valuable series of observations on concussion of the spine. He also contributed to the subject of hydrophobia. Dr. Watson was one of the leading practitioners of Jersey City at the time of his death.

Death of Dr. Hunt, of Port Jervis.—Dr. J. Halsey Hunt, a prominent physician of Port Jervis and the founder of the Hunt Memorial Hospital, died in Salt Lake City, Utah, on December 21st, of apoplexy. Dr. Hunt was making an extended trip to the Pacific slope and Alaska. Dr. Hunt was a son of the late Dr. Isaac S. Hunt, and was born in Sussex County, N. J., in 1848. He erected a hospital in Port Jervis in 1889, and was Erie Railway surgeon until recently. He was also a director in the First National Bank of Port Jervis and the Electric Light Company.

The Typhoid Epidemic in St. Louis.—*The Weekly Medical Review* does not accept the view that the water-supply is the cause of the present epidemic of typhoid

fever in St. Louis. It says: "So far as its limitation to St. Louis is concerned, we have nothing to justify the assumption. In various localities it prevails to an alarming degree. In Massachusetts as well as in New Mexico there are numbers of marked cases; and the student of sanitary reports will find that in this country typhoid fever exists in a much more marked degree than it has for some years past. The prevalence is such that a common belief has sprung up that it is merely a forerunner of Asiatic cholera next year. Of course such is not the case, but the cause of the present prevalence is certainly mysterious. Thus, we do not seem to be able to find any adequate reason for the existence of typhoid fever in St. Louis. The water has been examined, premises inspected, and no particular condition discovered which would account for it."

Not Americans.—*The Medical Times and Register* says the effrontery with which the English journals foist their disreputable brothers upon America is quite amusing. Neill, or Cream, the "American" poisoner, happened to be born in Glasgow. Two Belfast rascals assumed the title of "The Faculty of American Physicians and Surgeons," and started to do up their countrymen. While they were speedily exposed, and every one is aware that they never saw America, the English journals still keep harping on them as "the American doctors."

The Academie de Médecine of Paris is to follow the example of other great metropolitan medical societies and have a new and finer building, formerly occupied by a pawnbroking establishment.

Remuneration of Medical Students who Served in the Hamburg Epidemic.—During the recent cholera epidemic in Hamburg a misunderstanding arose as to the remuneration of the medical students who volunteered their services. The dean of the medical faculty of Hamburg has now published the following: "The Cholera Commission of the Senate of Hamburg, in a letter addressed to the undersigned dean, expresses its thanks to all the students of medicine who assisted in combating the cholera epidemic, and at the same time intimates the wish to send the undermentioned fee to all those who worked in the Hamburg hospitals in the belief that their services were to be remunerated at the rate of twenty marks a day."

"The Telephone Ear."—We hardly needed Mr. Rudyard Kipling's vivid sketch of the life passed at the end of a telephone by the American millionaire in summer quarters to bring before us that latest outcome of a too keenly competitive civilization, the "telephone ear." That particular neurosis, which seems, in the New World at least, to be earning a place in classification with the "lawn tennis leg," had already been foreseen and described by Professor Lannois of the Lyons Medical School. For ears which are not especially sound he considers the telephone to be quite contra-indicated, as even in a comparatively robust organ its continuous use is followed by symptoms more or less grave—cephalalgia, vertigo, hyperæsthesia, insomnia, and sometimes psychical disturbances of a character which might become chronic. He counsels a sparing use of the instrument in the case of those whose ears are sound, and an absolute abstention from it in those whose organs are already impaired from causes hereditary or induced. His memoir, which was read and discussed in a confirmatory sense at the Congress of Aural Surgeons held in Paris in 1889, will be found in the "Comptes-Rendus et Mémoires," p. 265, for the same year.—*The Lancet.*

A Miracle Cure Exploded.—Archbishop Ireland recently dealt in a novel but most sensible way with a so-called miracle cure which was being exploited at Canton, Minn. The report was that a miraculous image of the Virgin and Child had appeared upon a pane of glass in the window of the church at Canton, and that infirm persons were making pilgrimages to the church. Thereupon the Archbishop gave orders that the matter should be investigated by a scientific expert whom he appointed. When the result of the investigation was made known to the Archbishop, a few days ago, he took the action in the case which is required by the laws of the Church, and the "miracle window" will not hereafter be seen. The expert found that a fraud had been perpetrated by a photographer of the place, who had subjected the pane of glass to a kind of treatment under which, by means of certain apparatus, the images were made to appear upon it. The expert also found that though many infirm pilgrims had been drawn to the place by reports that miraculous cures were performed there, not one of them had been relieved of his infirmity. He furthermore ascertained that a number of conscienceless men in Canton were allied with the photographer, and had mercenary reasons for trying to keep up the delusion.

Several Prominent Russian Physicians presented M. Pasteur with a costly gift on his seventieth birthday, which occurred on December 27th.

Kissing the Book in taking an oath is regarded by sanitarians as dangerous. In England one can be sworn with uplifted hand. Such is the practice here before a notary. It is also a fact that actual contact of lips with the book is not insisted upon in our courts.

France Has a New Medical Law.—It abolishes the grade of officier de santé, and makes it necessary for everyone who wishes to practise medicine in France to have a diploma obtained by examination before the Faculty of Medicine. Foreigners who possess a medical degree are exempted from certain parts of the examination. The notification of infectious diseases is made compulsory.

The Medical Students at Barcelona University have struck because of the scarcity of patients. The medical students of Athens have struck because the fees were too high.

The Fatality of Wet-nursing.—Mr. Tyndall has been giving some startling statistics concerning nursing as a livelihood. A healthy girl, seventeen years of age, he says, who becomes a nurse, dies twenty-one years sooner than a girl of the same age moving in the general population. That is to say, a hospital nurse, twenty-five years of age, has the same expectation of life as a person fifty-eight years of age has, who is a member of the community at large. Everyone is aware of the additional risks that inhere in the service of the trained nurse, but these facts are sufficiently startling. It is not probable, however, that they will deter many from the career, but they

will increase the appreciation of the public for the self-sacrifice, and often personal heroism, of the hospital nurse.

A Death Recently Occurred in England from Eating Canned Sardines.—The patient was a robust young man and he died with symptoms of acute alkaloidal poisoning. Chemical investigation showed that the poison was a ptomaïne or toxin due to decomposition. In the MEDICAL RECORD, some years ago, a note was published of a family seriously poisoned by eating sardines. No death occurred, however.

Lunatics and Epileptics abound in the Imperial family of Austria. It is stated that with the sole exception of the Emperor himself almost everyone of the archdukes and archduchesses belonging thereto is subject, in a greater or less degree, to fits of epilepsy.

"Roaring" in Horses is due to a paralysis of one of the dilators of the glottis, with a falling forward and downward of the arytenoid cartilage. French surgeons cure the trouble by extirpating the cartilage.

Music has a special effect on the vaso-motor functions and heart action. The violin, harp, and pianette, with a little vocal harmony, have the best effects. Music is indicated in the functional angiopathies.

Symphytrotomy has been done for the first time in the United Kingdom, by Dr. W. J. Smyly, of Dublin. The case was successful.

Italian Organ-grinders and their Children.—It is stated by Italian journals that there exists in Italy the practice of selling children to itinerant organ-grinders for service as performing children in the streets of New York, Paris, Berlin, and Vienna. In France, Belgium, and England, out of 1,000,000 children 280,000 die before their tenth year; in Italy the number is 480,000.

Death Through Laughter.—A curious case of accidental death formed the subject of investigation before a coroner's jury recently, the ostensible cause of the fatality being the act of laughing, in which the deceased, at the London County Lunatic Asylum, was indulging at the moment of death. In company with two other attendants she was engaged in conversation, in the course of which an amusing story was narrated, the effect of which was to create irresistible laughter on the part of the deceased nurse, who, in the effort to repress her excessive mirth, bent forward as though to stifle it, and forthwith died. The post-mortem examination subsequently made of the body showed that the cause of death was an accumulation of pericardial fluid, by which the free action of the heart was so much impeded that the extra strain produced by the attempt to stifle laughter resulted in its permanent cessation.

The Number of Doctors in Italy.—According to official statistics recently published in the *Bolletino della Direzione della Sanita Publica*, the number of medical practitioners in each of the principal cities of Italy is as follows: Turin with a population of 613,995 has 431 doctors, Genoa with 425,854 inhabitants has 240, Milan with 275,164 has 391, Venice with 149,686 has 124, Bologna with 354,584 has 215, Florence with 539,855 has 281 (?), Rome with 507,504 has 506, Palermo with 486,448 has 316, Messina with 238,294 has 117, while Naples with a population of 678,891 has 1,323. It will be seen, therefore, that Naples has the largest number of physicians, as well actually as in proportion to the population. But America still leads, and as long as two-year courses will secure a diploma, is likely to retain the lead.

Texas Medical College.—This institution does not seem to be the great success which it was anticipated to be by those who were most active in its establishment. At least we would judge so from what appears in Daniel's *Texas Medical Journal*, which says: A magnificent building was constructed, and every department thoroughly equipped for teaching modern medicine. An able faculty was secured, and a high and thorough curriculum was arranged, extending over three years' graded courses. No longer should it be a reproach to Texas that with her princely school fund and her university, where all else is taught, her sons were compelled to go abroad for medical education. After ever so many obstacles overcome, at last the doors of a magnificently prepared medical college were thrown open and students were invited to come in. They didn't come. The mistake was made by the Legislature. They—and not the Regents—as should have been the case, fixed the fees and fixed them too high. The fee is $140 per year. This is not high, but is higher than that of some other Southern colleges, hence Texas students get their diplomas elsewhere, and then come back to Texas to practise. The remedy proposed is to fix some restrictions upon the kind of medical diploma required to enable a man to practise in the Lone Star State.

The Treatment of Pneumonia.—Dr. Boardman Reed has expressed the following views: 1. Water locally applied, either by wet packs or in the form of baths, after the Brand method, is the most efficient single remedy or therapeutic measure for acute pneumonia. 2. Either veratrum viride or aconite can accomplish more than any other single drug in the first stage, and that the same is true of digitalis in the second stage. 3. A combination of one of these cardiac sedatives with opium and diaphoretics, affords not only a safe but an eminently successful internal treatment for the first stage of acute pneumonia, being capable of aborting the disease when its administration is begun near the onset, and is repeated at short intervals day and night. 4. Venesection, though a most efficient means of treating sthenic forms of pneumonia, and, judiciously employed, considerably more successful than any merely expectant method, is no longer an indispensable resource in managing the disease, since other remedies have been found to accomplish the same results more surely and pleasantly.—*Therapeutic Gazette.*

Doctors and Newspapers in San Francisco.—The San Francisco County Medical Society has adopted a resolution "that any member of this Society whose name shall appear in the daily press, describing his professional powers in an unprofessional manner, and who cannot give a satisfactory explanation of the same shall at the next meeting be expelled from the Society." The Society recently punished four members for permitting interviews of this kind.

The Palmist is the title of a new chirological review (not to be confounded with the "Psalmist") published in London in the interests of scientific palmistry.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Adjourned Annual and Stated Meetings, November 28, 1892.

DR. G. H. FOX, AFTERWARD DR. C. C. LEE, IN THE CHAIR.

Report of the Censors.—This report was read by DR. VAN SANTVOORD, and included that of the counsel for the Society, Mr. Purrington. The amount of the fines imposed by the courts upon illegal practitioners had somewhat exceeded that of last year.

"The Medical Directory."—DR. DANIEL LEWIS, editor of the "Directory," read his report. The growth of the "Directory" was shown by the fact that the first issue, in 1885, contained 28 pages, while the issue for the present year contained 246 pages. In was, in fact, the standard "Medical Directory" for the city, containing the only complete and authentic list published. It had led to a large accession of membership and to prompt payment of back and current dues. The income from the advertisements somewhat exceeded the cost of publication. This report was accepted and a vote of thanks extended the editor.

Address of the Retiring President.—DR. FOX said he had had the honor to be the fiftieth President of the Society. During the year, owing to the efficient work of the comitia minora, the Society had prospered even more than during previous years; there had been a greater accession of members, and the number and value of the papers had given every reason for satisfaction. Limiting the length of papers to twenty minutes' reading, and individual discussions to five or ten minutes, had made it possible to present much valuable matter in a short space of time. Medicine was broad, and the science as it stood to-day had been built up from the facts acquired during the past ages, and especially during the present epoch-making generation. Still, there were those who wished to impose upon the people for gain, and practised without legal or scientific qualification. The Society had done much good for the public in ridding it of such impostors. Unfortunately there were also a number, legally qualified, who resorted to outrageous methods of advertising.

After expressing his faith in the future prosperity of the Society, he introduced the President-elect.

Address of Dr. Lee.—On calling the Stated Meeting to order the newly elected President, DR. CHARLES CARROLL LEE, expressed appreciation of the very great compliment paid him when he was elected to the highest office in the gift of the Society, especially as he had not been active in the councils of the Society and had done little to merit the suffrages of its many members. He could promise little, but would serve the Society to the extent of his ability.

Committees.—The following committees were appointed: *Ethics*, Drs. Everett Herrick, Laurence Johnson, W. H. Katzenbach, F. W. Jackson, J. West Roosevelt; *Hygiene*, Drs. W. A. Ewing, R. T. Morris, E. H. Grandin, J. T. Nagle; *Prize Essay*, Drs. E. B. Bronson, Beverley Robinson, Samuel Lloyd; *Auditing Committee*, Drs. G. T. Jackson, W. P. Northrup.

Modern Antiseptic Method of Removing Mammary Cancer.—DR. ROBERT F. WEIR read a paper with the above title (see p. 752).

A Limited Incision a Brutal Operation.—DR. A. G. GERSTER had found, when assisting beginners, that they made the incision for removal of the cancerous breast too small, and being hampered during the entire operation they bruised the tissues; this encouraged more rapid dissemination of any possible remaining cancerous material, and did the patient more harm than benefit. One bugbear in the operation had been fear of injuring the axillary vein, but with a free incision nothing was easier than to expose this vessel. For the last year and a half he had closed the wound entirely, using no drainage, and union had always taken place without fever or suppuration, which formerly had given more or less trouble.

DR. ROBERT ABBE said he now made his incision in the axilla somewhat lower, and thus avoided the necessity for a counter-opening for drainage, and sought primary union without employing the drainage-tube. A very large wound could be closed by Thiersch's dressing. He had wounded the axillary vein in one case because of its involvement in the cancerous growth, and his house-surgeon, in another, to a distance of an inch and a half, but sewed it up longitudinally with fine silk, and there had been no trouble afterward.

DR. BECK presented two women on whom he had operated for cancer of the breast. One was first operated upon in 1888, and illustrated the need of quick removal of recurring nodules, as she was still in comparatively good health although put under the knife four times.

DR. DANIEL LEWIS had observed that when the axillary vein was involved recurrence took place soon, and he therefore counselled against ligation and excision. He would rather abandon the operation. He fixed the arm only, leaving the forearm free, as it gave the patient greater comfort. Like Dr. Abbe, he made the axillary incision lower than Dr. Weir had represented, and thereby was able to dispense with drainage.

Resorcin in the Treatment of Chronic Gastritis.—DR. WILLIAM H. THOMSON gave his personal experience in private practice from 1886 to January, 1892, with resorcin in the treatment of chronic gastritis. Only such cases were included as had pronounced gastric disorder. They numbered 78, 41 of whom were females. The failures out of the 78 cases were 21; doubtful, 6; successes, 51. Where the gastric trouble was consecutive to nervous disorder the resorcin had no affect; not so when the nervousness was secondary to the gastric disturbance. Of the successful cases 17 presented symptoms of gastric ulceration. Four of the cases without evidence of ulceration belonged to what he called "railroad dyspepsia," meaning thereby dyspepsia arising from bolting food in order to make train time between city business and suburban home. The resorcin here was a success, of course with correction of the faulty habits. Four of the cases were in persons subject to migraine, and while the resorcin did not relieve the attacks of headache, it did act as a prophylactic. The benefit of an antiseptic like resorcin in these cases seemed to support the view that the element of intermittency which separated functional from organic nervous diseases pointed to a toxic origin for the former. Two of the patients benefited by resorcin had gastritis following grip. He rarely prescribed more than five grains, never in powder, but always in solution.

An Antiseptic, Anti-Fermentative, and Germicide.—DR. ANDREW H. SMITH thought resorcin possessed decided antiseptic, anti-fermentative, and germicidal powers, and at the same time it could be taken into the stomach in considerable amount without danger; one hundred and fifty grains had not caused death. The remedy was indicated in cases calling for these effects; besides, like carbolic acid, it possessed some anæsthetic effect on the terminal nerves in the stomach, and this might account for its power to arrest nausea. It would seem that a number of nervous troubles were the result of absorption of toxicants from the stomach and gastro-intestinal tract, and if this were true the field for resorcin would be a wide one.

DR. WILLIAM H. FLINT was convinced of the usefulness of resorcin in the class of cases related in the paper. In order to prolong the antiseptic effect beyond the stomach, he sometimes added salol, or creosote, protected so that it would reach the intestine. A drachm dose of a three per cent. solution of peroxide of hydrogen, fifteen minutes before meals, was useful in some cases.

INDEX.

A

Abdominal cavity, needle in the, 259.
Abdominal operations, purgatives after, 191.
Abdominal organs and tissues, abnormal conditions of, simulating disease of the uterus and its appendages, 601.
Abdominal section, for diagnostic purposes, 415; in pelvic peritonitis, 519.
Abdominal surgery, complications during and after operation in, 405; treatment of the peritoneum in, 605; what makes for success in, 661.
Abortion, criminal, among married ladies, 572; criminal, not murder in Germany, 737; habitual, assafœtida for, 494; in an hour, 339; treatment of, 172; tubal, 661.
Accouchement forcé in certain obstetrical complications, 407.
Accounts, physicians', 718.
Acne, treatment of, 36.
Actinomycosis, 78; treatment of, 352.
Actors, longevity of, 251.
Adenitis, a severe case of suppurative, 703.
Adenoids in the naso-pharynx in children, 183.
Adulteration of food, 341.
Advertiser, taking an, at his word, 384.
Advertising, medical, in England, 55.
Aëronautic casualties, 47.
Agathin, a new analgesic, 424, 514.
Aged, operations on the, 596; ovariotomy in the, 689; phthisis in the, 681.
Air in the veins, 25.
Air-passages, upper, use of sprays in the treatment of catarrhal affections of the, 107.
Aitken, Sir William, death of, 18.
Akinesia algera, 139.
Albertson, William C., the use of smoke as a curative agent in pulmonary phthisis, 444.
Albuminuria in epilepsy, 352.
Alcohol, vital statistics of total abstainers from, 84.
Aleuronat for diabetics, 311.
Allen, Charles W., impressions of some of the newer drugs in dermatological practice, 92.
Alopecia areata, treatment of, 280.
Aluminium, artificial limbs of, 551.
Alumni Association of Charity Hospital, officers of, 737.
Amblyopia, toxic central, terminating in progressive atrophy, 70, 104.
American Gynecological Society, 405.
American Health Resort Association, 131.
American Laryngological Association, 105.
American Medical Association, 21; union of, with the Canadian, 748.
American Neurological Association, 133.
American Ophthalmological Society, 197.
American Orthopedic Association, 436.
American Otological Society, 165.
Amœba coli, demonstration of, in the tissues, 461; dysentery due to, 756; importance of, in diagnosis and prognosis, 714.
Amputation, a modification of Teal's rectangular flap operation in, 248; a retractor for use in, 140, 261; and resection, primary consecutive, in traumatisms of the extremities, 67.
Anæmia, treatment of, 28.
Anæsthesia, hypodermic, 79; production of local, 493; the introduction of, 719.
Anæsthetic, a new local, 425.
Anæsthetics, collective investigation on, 79.
Anastomosis, intestinal, 257; intestinal, and approximation without sutures, 665; intestinal, by a new device, 687.
Anderson, R. Harcourt, graphospasmus, 361.
Andrews, Joseph A., an instrument for syringing out cortical matter in cataract extraction, 350.
Aneurism of the abdominal aorta, rupture of, into the psoas muscle, 430; of the aorta, treatment of, 458.
Angiokeratoma, 480.
Anglo-American Medical Association, 627.
Ankle-joint, complete erosion of the, 606.
Anorexia nervosa and hysterical trembling, 136.
Anthracosis, 289.
Anthropology, exhibit of, at the World's Fair, 391.
Anti-cancer League, 195, 626.
Antifebrine in scarlet fever, 481; toxic effects of, complicated with alcoholism, 511.
Antimony in skin-diseases, 478.
Antipyretics, an investigation of three, 421.
Antipyrine in epistaxis, 623; incompatibles of, 47, 443; smuggling, 220.
Antiseptic surgery, advances in, 23.
Antiseptics in abdominal surgery, 661.
Antitoxins, influence of, in the cure of disease, 170.
Anus, procto-plastic operation for the cure of cicatricial stenosis of the, 506.
Aorta, dilatation and atheroma of the, 378.
Apoplexy of the medulla oblongata, 547.
Apothecary's oath, 132.
Appendicitis, a plea for less surgical treatment of, 213; death from pulmonary embolism following operation for, 14; treatment of, 150.
Appendix vermiformis, lesions of, demanding surgical interference, 629.
Archivos de la Policlinica, a new journal, 711.
Aristol in dermatology, 93.
Armstrong, S. T., syphilitic hemiparaplegia, 31, 50.
Army, examination for the medical department of the, 599.
Arsenical wall-papers in England, 131.
Artists, psychology of, 480.
Ascites, 319; circumscribed, simulating ovarian tumor, 715.
Ashmead, Albert S., yellow fewer and the negro, 261.
Association of Medical Officers of the Militia of Canada, 27.
Asthma, nasal, alternating with circumscribed œdema of the skin, 539: neurotic, early symptoms of, 539; treatment of, 354.
Astigmatism, prevalence of corneal, in eyes with normal acuity of vision and without asthenopia, 615.
Asylum superintendent, insanity of an, 384.
Asylums, female physicians and the, 217.
Ataxia, hereditary, 593.
Athletic exercises as a cause of disease of the heart and arteries, 745.
Atropine, action of, upon the heart, 709.
Auscultation, in children, importance of attitude in, 679; intra-thoracic, 605, 625.
Australia, the medical profession in, 628.
Ayres, Edward A., a fecund family, 26.

B

Bacon, Leonard W., Jr., a common-sense bed-pan, 691.
Bacteria, and disease, 428; fighting mice with, 56; improved method of photomicrography of, 698; of phosphorescence, 565.
Baldness, treatment of, 421.
Balloch, Edward A., ectopia testis, with an illustrative case, 157.
Bandl, Dr. Ludwig, death of, 316.
Bangs, L. Bolton, blood in the urine, how to discover its source and what to do for it, 525.
Bank-notes, bacteria on, 253.
Bard, Cephas L., an improved iodoform box, 204.
Barham, Cuthbert R., a study of neurotic eczema in adults, 37.
Barnum, M. W., complete atresia of the cervical canal resulting from syphilitic ulcers, 190.
Barrett, W. C., the microbicidal action of tobacco smoke, 262.
Baths, cold, in tetanus, 680; permanent warm, employed in articular inflammation, 507; the "People's," in New York, 316; the use of sulphur, 756.
Baumster, H. M., the death-rate of Chicago, 718.
Becelaere, J. V., a retractor for amputations, 261.
Bed, how to go to, 660.
Bed-bugs as carriers of tubercle bacilli, 347.
Bed-pan, a common-sense, 691.
Bedford, Professor Peter W., death of, 131.
Beer-drinking and cholera, 440.
Belfield, William T., on the use of iodine trichloride in surgery, 66.
Bennett, O. Prescott, the falsetto voice, 536.
Bequests to physicians, legality of, 627.
Beri-beri in New York, 657.
Berlin, incomes of physicians in, 543; letters from, 225, 349, 439, 606, 746; medical work in, 355.
Bettman, Boerne, a new operation for the speedy ripening of immature cataracts, 122.
Bevan, D., a test reaction for the culture of the micrococcus pyogenes aureus, 70.
Billroth, Professor, jubilee of, 543, 607; memorial tablet in the birthplace of, 515.
Birdsall, Dr. W. R, resolutions on the death of, 48.
Bismuth, oxyiodide of, in dermatology, 92; salicylate of, in infantile diarrhœa, 192.
Bissell, Joseph B., daytime enuresis in children, 697.
Bladder, "caisson working" in the surgery of the, 690; diagnosis of tumors of the, by microscopical examination, 431; extraction of a bottle from the, 279; phenacetine for irritation of the, 593; pledget of cotton in the, for seven years, 690; rare malformation of the, 378; stone in the, formed around a piece of catheter, 517; tumors of, in children, 510; tubercular ulceration of the, 660.
Bleeding from the skin, 635.
Blindness, causes of, 484.
Blood, alkalimty of the, in disease, 480; in the urine—how to discover its source and what to do for it, 525; feigned

vomiting of, 744; new method of examining specimens of, 249; physiology and pathology of destruction of the, 716, 744; rotation of the, 218; white corpuscles as protectors of the, 678.
Blood-serum therapeutics, Behring on, 292.
Blood-serum treatment of pneumonia, 540.
Board of Health, Report of the Conference Committee of the New York Academy of Medicine, 516.
Bond, R. I., chewing-gum in fevers, 1575; digitalis in pneumonia, 704.
Book Notices:
Treatise on gynecology, medical and surgical, by S. Pozzi, M.D., translated from the French edition under the supervision of, and with additions by, Brooks H. Wells, M.D., 18.
A primer of materia medica for practitioners of homœopathy, by Dr. Timothy Field Allen, 19.
A treatise on diseases of the nose and its accessory cavities, by Greville Macdonald, M.D. London, 19.
The science and art of midwifery, by William Thompson Lusk, A.M., M.D., 19.
The annual report of the State Board of Health for New Hampshire, for the year ending October 31, 1891, 19.
A text-book on the practice of medicine, for the use of students and practitioners, by R. C. M. Page, M.D., 19.
Outlines of zoölogy, by J. Arthur Thomson, M.A., F.R.S.E., 20.
Fifteenth annual report of the Board of Health of New Jersey, 1891, 20.
Chirurgische Technik, Ergänzungsband zum Handbuch der kriegschirurgischen Technik enthaltend die übrigen Operationen, von Dr. Fr. von Esmarch und Dr. E. Kowalzig, 20.
Traité pratique de gynécologie, par Dr. A. Auvard, 20.
Transactions of the American Orthopedic Association, fifth session, vol. iv., 20.

The extra pharmacopœia, by William Martindale, F.C.S.; medical references and a therapeutic index of diseases and symptoms, by W. Wynn Westcott, M.B. London, seventh edition, 375.
Uric acid as a factor in the causation of disease, by Alexander Haig, M.A., M.D. Oxon., F.R.C.P., 404.
Text-book of the eruptive and continued fevers, by John William Moore, B.A., M.D., M.Ch. Dublin, 404.
De la périnéotomie et de ses applications, par le Dr. Charles Uillems, assistant à l'université de Gand, 404.
Transactions of the American Pediatric Society, edited by William Perry Watson, A.M., M.D., 404.
Elements of materia medica and therapeutics, including the whole of the remedies of the British Pharmacopœia of 1885, and its appendix of 1890, by C. E. Armand Semple, B.A., M.D. Cantab., M.R.C.P. London, 404.
A practical treatise on diseases of the skin, by John V. Shoemaker, A.M., M.D., second edition, 485.
Book on the physician himself and things that concern his reputation and success, by D. W. Cathell, M.D., tenth edition, 485.
Transactions of the Medical Society of the State of New York, 1892, 485.
The American text-book of surgery for practitioners and students, edited by William W. Keen, M.D., LL.D., and J. William White, M.D., Ph.D., 485.
Regional anatomy in its relation to medicine and surgery, by George McClellan, M.D., vol. ii., 486.
Transactions of the eighth annual meeting of the American Climatological Association (1891), 486.
Spondylolisthèsis et spondylizème, résumé de recherches littéraires et personnelles depuis 1880 jusqu'en 1892; par le Dr. François Neugebauer (de Varsovie), avec introduction par le Professeur A. Charpentier, 486.
Book Notices:
Geographical pathology, an inquiry into the geographical distribution of infectious and climatic diseases, by Andrew Davidson, M.D., F.R.C.P. Ed., 486.
A manual of chemistry, inorganic and organic, with an introduction to the study of chemistry, by Arthur P. Luff, M.D., B.Sc. (London), M.R.C.P., 486.
The essentials of histology, descriptive and practical, for the use of students, by E. A. Schäfer, F.R.S., third edition, revised and enlarged, 486.
A handbook of hygiene and sanitary science, by George Wilson, M.A., M.D., F.R.S. Edin., D.P.H. Camb., seventh edition, 487.
Diseases of the stomach, by Dr. C. A. Ewald, authorized translation by Morris Manges, A.M., M.D., 487.
Transactions of the thirteenth annual meeting of the American Laryngological Association, held in Washington, D.C., September, 1891, 487.
Cancer of the mouth, tongue, and œsophagus; their pathology, symptoms, diagnosis, and treatment, by Frederic Bowreman Jessett, F.R.C.S. Eng., 488.
The manual of obstetrics, by A. F. A. King, A.M., M.D., fifth edition, 488.
Diseases of women: a manual of non-surgical gynecology, designed especially for the use of students and general practitioners, by F. H. Davenport, A.B., M.D., second edition, 488.
Public health papers and reports, vol. xvii., 488.
A text-book of the principles and practice of medicine, for the use of medical students and practitioners, by Henry M. Lyman, A.M., M.D., 488.
Temperament, disease, and health, by French Ensor Chadwick, Commander U.S.N., 488.
Essentials of medical diagnosis, by S. Solis Cohen, M.D., and Augustus A. Eshner, 657.
Transactions of the Medical Association of Georgia, forty-third annual session, 1892, 657.
Fourteenth annual report of the State Board of Health of the State of Connecticut, for the year ending November 30, 1891, edited by Charles A. Lindsley, M.D., 657.
Colotomy—inguinal, lumbar, or transverse, for cancer or stricture with ulceration of the large intestine, by Herbert W. Allingham, F.R.C.S., 657.
Surgical treatment of neuralgia of the fifth nerve, by William Rose, M.B., F.R.C.S., 657.
The student's handbook of surgical operations, by Frederick Treves, F.R.C.S., 657.
A treatise on hygiene and public health, by Thomas Stevenson, M.D., and Shirley F. Murphy, vol. i., 657.
Proceedings of the United States Naval Institute, vol. xviii., No. 3, 1892, 657.
The pocket pharmacy, with therapeutic index, a résumé of the clinical applications of remedies adapted to the pocket-case, for the treatment of emergencies and acute diseases, by John Aulde, M.D., 739.
The principles of theoretical chemistry, with special reference to the constitution of chemical compounds, by Ira Remsen, fourth edition, 739.
An illustrated encyclopædic medical dictionary, being a dictionary of the technical terms used by writers on medicine and the collateral sciences in the Latin, English, French, and

Book Notices:
German languages, by Frank P. Foster, M.D., vol. iii., 739.
Index catalogue of the library of the surgeon general's office, U.S.A., authors and subjects, vol. xiii, 740.
A manual of organic materia medica, being a guide to materia medica of the vegetable and animal kingdoms, for the use of students, druggists, pharmacists, and physicians, by John M. Maisch, Ph.M., Phar.D., fifth edition, 740.
A treatise on diseases of the nose and throat, in two volumes, by Francke Huntington Bosworth, A.M., M.D., vol. ii., diseases of the throat, 740.
Boro-borax, 584.
Bosley, Dr. George H., obituary of, 684.
Bottome, Frank A., a severe case of suppurative adenitis, 703.
Bowels, colorless motions from the, 755.
Bradbury, S., the power of sulphate of magnesium in curing catarrhal inflammation of the digestive track, 43.
Bradycardia and the action of atropine on the heart, 709.
Brain, a dog without a, 383; abscess of the, 78; atrophy of one hemisphere of the, 433; extensive pistol-shot injury of the, 341; gunshot wounds of the, 23, 378; localization of the action of remedies upon the, by intranasal medication and compression of the internal jugular veins, 749; localization of tumors of the, 716; minute hemorrhages of the, 433; of a Chinese, 136; operative procedures at the base of the, 23; otic disease of the, 489; perimeter measurements in the diagnosis of local disease of the, 321; sensory-motor functions of the, 238; sexual differences in the, 132; sexual differences in the, and high-school education, 45; the criminal, 136.
Brandegee, William P., a combined post-nasal spray and palate retractor, 579.
Breast, carcinoma of the, following traumatism, 461; excision of the, 428; how amputation for carcinoma of the, should be performed, 752, 761; inflammation of the, compression corset for, 171; some observations on cancer of the, 573.
Bright's disease, dyspnœa of advanced, 192, 652; chronic, treatment of, 385; lesions of, 52; regimen in, 484.
British Medical Association, 229; admission of women to the, 290, 312; annual addresses before the, 168; section on medicine, 318; section on obstetric medicine, 285; section on public health, 322; section on surgery, 254.
Bronchial casts in fibrinous bronchitis, 289.
Bronchitis, tuberculous, treatment of, 353.
Broncho-pneumonia, tuberculous, 320.
Bronson, Edward Bennet, origin of type in disease, 441.
Brothers, A., notes on two cases of spontaneous intermittent hemorrhage, 362.
Broun, LeRoy, fifty selected cases from the practice of Dr. Clement Cleveland, at the Woman's Hospital of the State of New York, 499.
Bryant, Joseph D., fourth laparotomy on an hysterical patient, 726, 745.
Buchanan, Sir George, a testimonial to, 219.
Buck, Albert H., a contribution to the technique of mastoid operations, 96.
Bull, Charles Stedman, traumatic irido-choroiditis, ending in intra-ocular glioma, 189.
Burns, europhen in, 353; in children, treatment of, 680; treatment of, 419.

C

Caddy, Arnold, excision of the inner two-thirds of the right clavicle for sarcoma, 586.
Cæsarean section, elective, 459; most favorable time for, 405; prevention of hemorrhage in, 285.
"Caisson working" in bladder surgery, 690.
Calcium salts, therapeutic value of, 493.
Camphoid, 190.
Canada, letter from, 747; quarantine in, 460; the military surgeons of, 104.
Cancer, a new parasite in, 182; and erysipelas, possible antagonism of, 403; autoinfection of, 351; chimney-sweeps', alleged decline of, 173; collapse of the Mattei treatment of, 290, 307, 404; league against, 195, 626; micro-organisms of, 47; of the breast following traumatism, 461; of the breast, how amputation for, should be performed, 752, 761; of the breast, some observations on, 573; of the femur in a boy thirteen years old, 44; of the ileum, excision of, 745; of the larynx, partial laryngectomy for, 631; of the liver, 223; of the rectum, 256; of the rectum, medical treatment of, 595; of the stomach, operations for, 15; of the uterus, operations for, 408; of the uterus, vaginal hysterectomy for, 29, 30, 49; parasitic origin of, 571; pastes for, 423.
Cannabis indica in the painful diseases of women, 155.
Capparelli, Dr. Leonzio, a medical novelist, 355.
Capsicum in hiccough, 348.
Carbolic acid, antidote for, 493.
Carbuncle, treatment of, by injection of carbolic acid, 455.
Carotid, common, ligature of the, 256.
Carr, Walter Lester, a case of scorbutus in an infant, 419.
Cartilage, inflammation of, 436.
Castle, F. A., physicians' accounts, 718.
Castor-oil, palatable, 383.
Castration for melancholia, 736.
Cataract, instrument for syringing out cortical matter in extraction of, 350; new shield for the protection of the eyes after operation, 664; operation for the speedy ripening of immature, 122; statistics of some operations for, 172.
Catarrh, intestinal, sulphate of magnesium in, 43; nasal, snuffs for, 494.
Catgut, an apparatus for the sterilization of, 648, 748.
Catheter, an improved, 175.
Cellulitis, malignant, 537.
Cemeteries, sanitation of, 157.
Cerebral artery, middle, thrombosis of the, 288.
Cerebral development, pathology of arrested, 135.
Cerebro-spinal disturbances in women, relation of the organs of reproduction to, 715.
Cervicitis, various forms of, 689.
Chancre of the eyelid, 535; of the mouth, 393.
Chancroid, microbe of, 281.
Chapped hands, application for, 354.
Charaka Samhita, 458, 485.
Chase, Dr. Enoch, death of, 316.
Cheesman, William S., ovariotomy in the presence of peritonitis, 308.
Chemistry, bearing of, on medicine, 491.
Chest, prognosis of gunshot wounds of the, 455.
Chicago, the sanitary condition of, 46, 217, 633, 718.
Child, a matured, 72.
Child-bearing, asthenia from, 292; factory operatives and, 322.
Child-birth, facilitation of, in the Kirghiz, 328.
Children, adenoids in the naso-pharynx in, 183; daytime enuresis in, 697; exhibit of appliances for, at the World's Fair, 738; hygiene of, 510; importance of attitude in the auscultation of, 679; methylene blue in three cases of malaria in, 191; new born, stomatitis due to irritation of epithelial pearls in the mouth of, 411; treatment of burns in, 680; vesical tumors in, 510; vulvo-vaginitis in, 707.
Chili, medical journalism in, 140.
Chimney-sweeps' cancer, alleged decline of, 173.
Chinese, brain of a, 136; medical ideas of the, 477.
Chloroform and ether question, a contribution to the, 74; treatment of heart-failure from, 344, 368; inhalers, a new feature of, 608; narcosis, induction of, during sleep, 603; narcosis, treatment of suspended animation in, by insufflation in the inverted position, 340.
Chlorosis, sulphur in, 264.
Cholagogues, action of, 745.
Cholecystitis, suppurative, 248.
Cholecystotomy, 690.
Cholera, a post-mortem phenomenon in, 383; and Cuban quarantine, 619; and fright, 459; antiseptics in, 402; bacillus of, see *Comma bacillus;* Cantani method of treating, 403, 439; clinical history of the first case of, in New York, 420; clinical observations on two cases of, 531; cremation of those dead from, 384; criminal treatment of, 736; disinfection in, 389, 741; evacuant treatment of, 368; explanation of the epidemic of, at Hamburg, 371; in England, 463; in Hamburg, 430, 654; in London, 379; in New York in 1832, 492; in Paris in 1892, 720; in Srinagar, 321; local measures of prevention of, in New York City, 376; lysol in, 367; mercury in, 633; mortality from, 371; onions in, 684; quinine in, 399, 676; practical experiments in the treatment of, in St. Petersburg and Hamburg in the epidemic of 1892, 693; precautions for nurses and physicians, 372; prophylaxis and treatment of, 434; preventive measures against, 349, 747; preventive inoculations against, 219, 370, 401, 711; previous epidemics of, in the United States, 369; progress of the epidemic of 1892, 48, 103, 129, 161, 193, 220, 250, 280, 312, 314, 344, 373, 737; regulations concerning, 282, 284; strychnine in, 284; the latest story anent, 720; the practitioner and, 376; the section in public health of the New York Academy of Medicine on, 370, 375; tobacco as a preventive of, 711; treatment of, 284, 337, 365, 367, 371, 380, 399, 403, 434, 439, 440, 548, 633, 676, 692; treatment of, at Havre, 513; treatment of, on Swinburne Island, 741; treatment of, based on the experience gained in the Hamburg epidemic, 606; treatment of the algid stage of, 494; vaccination against, 219, 370, 401, 711.
Cholera morbus, treatment of, 435.
Chorea, Huntington's, 222; Huntington's, congenital, 137; in a negro, 215; post-influenzal, 495; treatment of, 400, 493.
Choroiditis, metastatic, 245.
Christian science and divorce, 598.
Chronic diseases, precision in the treatment of, 721.
Cigarette epidemic, 328.
Cimicifuga in uterine disorders, 291; indications for the use of, 680.
Circle of Willis, a social organization, 459.
Circumcision for papillomatous growths on the prepuce, 25.
Cirrhosis, hæmatemesis in, 435.
Clark, Dr. Henry Grafton, death of, 402.
Clark, S. S. P., the lost art of venesection, 33, 162.
Clark, Sir Andrew, and doctors in politics, 655.
Clavicle, excision of the inner two-thirds of the, for sarcoma, 586; treatment of fracture of the, 214.
Club-foot, etiology and treatment of, 437; modern treatment of, 714; treatment of, 528. See also *Talipes.*
Cocaine, anaphrodisiac effect of, 354; cantharidinate of, 515; in tinnitus aurium due to middle-ear disease, 479; sub-conjunctival application of, 200.
Cocainism, 474.
Cock, Mr. Edward, death of, 463.
Cocks, G. H., traumatic injuries to the eye, 555.
Cœliotomy after labor, 406.
Cohn, I. E., the Chinese and their peculiar medical ideas, 477.
Colectomy for closure of an artificial anus, 429.

Colic, hepatic, glycerine in, 435, 652; renal, exploration of the kidney for, 222.
College of Pharmacy, new building for the New York, 739.
Colon, irrigation of the, 427.
Columbus, medical history of, 482.
Colvis, Dr. Joseph, death of, 253.
Coma, treatment of diabetic, 159.
Comma bacillus, a test for the, 327; biological character of the, 387; destruction of the, in caviare and tobacco, 738; experiments in swallowing, 738, 746; observations on the viability of the, 413; quick method of distinguishing, 594.
Congo, doctors on the, 596.
Conjunctivitis, gonorrhœal, 565.
Connell, M. E., an experimental contribution looking to an improved technique in enterorrhaphy, 335.
Constipation, abdominal pressure for, 592; habitual, 128.
Consultant, a frank, 264.
Consumptives, sanitaria for the care of, 367.
Contagious diseases, weekly statement, 27, 83, 112, 140, 176, 204, 232, 264, 291, 328, 354, 383, 411, 440, 468, 495, 523, 551, 580, 608, 634, 692, 748.
Contract medical services, 521.
Contract surgeons, 76.
Cooper, O. O., report of a case of extensive pistol-shot injury of the brain—recovery, 341.
Coplin, W. M. L., a test-reaction for the culture of the micrococcus pyogenes aureus, 70.
Cork, George A., horse-shoe kidney, 589.
Cornea, general form of the human, 198; staining the nerves of the, 200.
Corning, J. Leonard, the localization of the action of remedies upon the brain by intranasal medication and compression of the internal jugular veins, 749.
Coronary artery, abnormal origin of the, 51.
Cough, some of the causes and the treatment of, 11.
Cowper's gland, cyst of, 605.
Cow, the, as an enemy of mankind, 490.
Cows, 355.
Craig, Thomas C., a small allowance of water per diem, 574.
Craniometric studies in relation to aural anatomy, 166.
Craniotomy, discussion of the justifiability of, 685.
Cream, Thomas Neill, the strychnine fiend, 597.
Creasote in soda water, 354; use of, in tracheotomy, 351.
Cremation at Glasgow, 636; in England, 348, 356, 552; in time of war, 341; of cholera victims, 384.
Creoline in dermatology, 94.
Criminals, reformatory treatment of, 101; the product of hereditary degeneracy, 96.
Croton water, 313.
Crowds, diseases and accidents of, 482.
Cuban medical congress, 283.
Culture and professional success, 544.
Curette, a modified Gottstein's, 291.
Cushing, Clinton, abdominal section for diagnostic purposes, 415.
Cystitis, ammonium benzoate in, 47; salol in, 353; treatment of, 520.
Cystocele, Stoltz's operation for, 286.

D

Dana, Charles L., a neurological outlook, 126.
Darwinism and disease, 21.
Davis, A. E., a study of 131 consecutive cases of enucleation, 445.
Dawbarn, Robert H. M., a new method of checking bleeding after tonsillotomy, 690; arterial saline infusion, 559.
Deaf children, teaching, to hear, 473.
Deafness, catarrhal, operation for, 167; labyrinthine, treated by pilocarpine, 191.
Death from a trivial accident, 140; movement to abolish the penalty of, 738; organic and somatic, 422; painlessness of, 552; sudden, due to fatty degeneration and dilatation of the heart, 261; the pain of, 457.
Deaver, Dr. J. M., death of, 252.
Debauch, tonic after a, 354.
Debtor, the doctor as a, 204.
Deformity, trade in, 26.
Delirium tremens, cause of, 55.
Delivery, post-mortem, 251; the sitting posture during, 652.
Denison, Charles, essentials of a good stethoscope, 494.
Dennis, Frederic S., the achievements of American surgery, 637.
Dentition, troubles of, 479.
Depilatory, formula for a, 353.
Dermatitis exfoliativa, case of, 591.
Dermatol in dermatology, 94; in diarrhœa, 565.
Dermatological practice, impressions of some of the newer drugs in, 92.
Deshon, Robert, clinical history of the first case of cholera in New York, 420.
Dessau, S. Henry, how sball we treat cholera? 380.
Diabetes mellitus, a new remedy in, 76; aleuronat in, 311; peculiar condition of the blood in, 259.
Diabetic coma, treatment of, 159.
Diagnosis, a case difficult of, 658; physical, a new departure in, 605, 625.
Diaphtherin, a new bactericide, 440.
Diarrhœa, choleriform, of young children, 548; dermatol in, 565; disinfection of the discharges in, 373; from retroflexion of the uterus, 735; infantile, salol in, 494; summer, salt for, 104; summer, treatment of, 353, 354.
Diet and digestion, influence of, on the voice, 713.
Digestion, influence of, on the voice, 713.
Digitalis and the digitalins, 570; in kidney disease, 539, 633; in pneumonia, 704; long-continued administration of, 430.
Dilator, cervical, of Champetier de Ribes, 286.
Diller, Theodore, two cases of neuritis, 534.
Diphtheria, 216; and allied pseudo-membranous inflammations, 113, 141; and its relationship, 585; etiology and treatment of, 611; from rags after nine years, 440; hydrogen peroxide in, 425; infectious, erythema in, 480; modern treatment of, 566; prevention of the spread of, 28; pyoktanin in, 706.
Disease, chronic, precision in the treatment of, 721; names, definitions, and classifications in, 549; origin of type in, 441.
Disinfectant, sulphur dioxide as a, 376.
Disinfectants, 493.
Disinfection, criticism of methods of, 369; directions for, 315.
Dislocations, diagnosis of, by sight, 662.
Dispensary abuse, a plan for the suppression of the, 230; in Germany, 225.
Docking horses, a veterinary surgeon fined for, 571; law against, 495.
Doctors, as popular leaders, 459; in politics, 655; number of, in the United States, 292; the emancipation of, 343; should they marry? 758.
Dog clinic in Philadelphia, 164.
Dog-meat, 496.
Doggerel, medical, 422.
Douche, nasal, substitute for the, 365.
Douglas, Dr. J. H., obituary of, 425.
Dowd, Charles N., an apparatus for the sterilization of catgut, 648.
Doyle, Dr. Conan, 220.
Drainage in surgery, the present status of, 689.
Dreifus, E., dysentery and ptyalism, 538.
Drowning, aural vertigo as an occasion of, 710; resuscitation in cases of, 328.
Drug stores in the United States, number of, 738.
Drugs, specific action of, 155.
Drysdale, Dr. John, death of, 252.
Dunham, Edward K., some observations on the viability of the cholera bacillus, 413.
Dunn, John, a modified Hartmann snare, 382.
Dwelling-house sanitation, 463.
Dysentery, amœbic, 756; and ptyalism, 538; repeated attacks of, associated with hepatic abscess, 377; treatment of, 128.
Dyspepsia, stray thoughts about, 472.
Dyspnœa of advanced Bright's disease, 192, 652.

E

Ear, disorders of the, in typhoid fever, 273; extension of disease of the, to the brain, 489; operations on the middle, 167; relation of aural and nasal affections, 148; removal of a bony growth from the external auditory canal by means of drills, 311; some new instruments for the, 262; treatment of discharges from the, 427.
Earache, acute inflammatory, 429; repeated attacks of, importance of determining the cause of, 715.
Earthworms and tuberculosis, 279.
Eaton, F. B., some practical uses of the ophthalmometer of Javal-Schiotz, 577.
Echinococcus cysts, iodoform emulsion in, 494.
Eclampsia, bacillus of, 226, 249; toxicity of the serum in cases of, 680.
Eczema, infantile, 27; neurotic, in adults, 37; solar, 480; treatment of, 35, 568.
Edgar, J. Clifton, intra-uterine injections of glycerine for the induction of labor and stimulating of uterine contractions, 620.
Edson, Cyrus, the propagation and preservation of vaccine virus, 391.
Education, as a therapeutic measure, 523, 580; southern medical, 292, 492.
Eggs by enema, 399.
Egotism, insanity of, 592.
Egypt, phthisis in, 320; wintering in, 205.
Elbow-splint, a fixation, 438.
Electrical methods as a substitute for surgery in certain pelvic affections, 428.
Electricity, a machine for the production of all kinds of, from a single storage battery, 262; use of, in midwifery, 729.
Electrode, a new flexible, 26.
Electro-therapeutics in Paris, 561; relations of a possible electric polarity of metabolism to, 265.
Ellis, R., the nervous sequelæ of typhoid fever, 398.
Elsner, S. L., treatment of chronic endometritis, 417.
Endocarditis, malignant ulcerative, 658; ulcerative, 519.
Endometritis, treatment of chronic, 417.
Enema, eggs by, 399; nutrient, 737.
England, conditions under which foreigners may practise medicine in, 323.
"English disease," the, 328.
Enterorrhaphy, an improved technique in, 335.
Enuresis, daytime, in children, 697; rhus radicans in, 707; treatment of nocturnal, in children, 570.
Epidermin, 132, 192.
Epilepsy, albuminuria in, 352; antirabic inoculation for, 125; caloric, 128; etiology of idiopathic, 133; hydrastinin in, 310; pilocarpine for, 47; sleep movements of, 133; surgical treatment of, 135.
Epileptic status, treatment of, 171.
Epileptics, separate provision for, 134.
Epistaxis, antipyrine in, 623.
Ergot, is it useless in obstetric practice? 757.
Erysipelas, phlegmonous, 537.
Erythromelalgia, 746.
"Escuela de Medicina," a new medical journal, 600.
Ether, an appliance for the administration of, 381; and chloroform question, a contribution to the, 74.
Ethmoiditis, suppurating, 107.
Eucalyptus honey, 28.
Eugenol-acetamide, a new local anæsthetic, 628.
Europhen, clinical observations on, 700; in burns, 353; in dermatology, 94.
Evans, Thomas R., dislocations at sight, 662; southern medical education, 492.
Evolution in disease, 21.
Exophthalmic goitre, 250.
Exophthalmos, pulsating, 200; treatment of, 354.

Expectoration, repression of, in public places, 130, 140.
Expert testimony, medical, proposed law concerning, 283.
Extension in the treatment of posterior spinal sclerosis, 192.
Eyelid, chancre of the, 535.
Eyes, appearance of the, in disease, 679; artificial, 455; gunpowder injury to the, 197; law of symmetry of the, 198; of California students, 540; of different colors, 279, 399; one hundred and thirty-one consecutive cases of enucleation of the, 445; traumatic injuries to the, 555; tuberculosis of the, 539; with normal acuity of vision, corneal astigmatism in, 615.

F

Factories, employment of married women in, 679.
Factory operatives and child-bearing, 322.
Faith-cures, the old time, 15.
Falsetto voice, 536.
Family physician, the ideal, 194.
Faster, insanity of a professional, 112.
Fasting for a medical college, 599.
Fecundity, remarkable, 26, 82.
Fee, cutting down a, by the court, 540.
Fees, large, 194; lawyers' and physicians', 710.
Femur, adduction following fracture of the, 436; fracture of the neck of, treated by the Thomas hip-splint, 565; malignant tumor of the, in a boy aged thirteen, 44
Ferguson, John, the diagnostic and prognostic value of tendon reflexes, 1.
Fevers, chewing-gum in, 575; feeding in, 620, 631; infectious, some complications and sequelæ of, 321.
Fibroids, uterine, and syphilis, 542; uterine, hysterectomy for, 409.
Filaria sanguinis hominis, photographs of, 51.
Fire-arms, surgical meaning of the new, 77, 83.
Fischer, Louis, a test for the comma bacillus, 327; treatment of diphtheria by pyoktanin, 706.
Fistula in ano, 622.
Fitch, George L., the etiology of leprosy, 293.
Fithian, Dr. Enoch, death of, 712.
Flatulence in stomach disorders, 249.
Flies, a death sentence on, 412.
Folie à deux and similar types of insanity, 137.
Foot, anomaly of the, 547.
Foot-ball mania, 567.
Forceps, value of, in complicated high arrest of the breech, 410.
Forrester, Joseph, eyes of different color, 399.
Fractures, intra-uterine, etiology of, 623; symptoms of, 687; treatment of compound, 26; treatment of ununited, by resection, 687.
France, higher medical degree in, 515; requirements for medical practice in, 231.
Freaks, the manufacture of, 215.
Freeman, Rowland Godfrey, the sterilization of milk at low temperature, with description of a new apparatus, 8.
Fruitnight, J. Henry, clinical observations on two recent cases of cholera asiatica, 531.
Fuchsine in dermatology, 94; in Paget's disease, 164.
Fuller, Dr. Fraser C., death of, 103; resolutions on the death of, 570.
Fuller, Robert M., an improved method of photo-micrography of hacteria and other micro-organisms, 698.
Fullerton, Erskine B., quinine in cholera, 399, 676.

G

Gallacetophenone in psoriasis, 353.
Gall-bladder, surgery of the, 254, 256, 497, 593; thickened, resembling cancer of the liver, 224.
Gall stones, 223.
Galvanic current, some minor therapeutic uses of the, 716.
Gambling for the benefit of hospitals, 74.
Gangrene, diabetic, question of amputating for, 604; of the lower limbs following intestinal obstruction, 550.
Garrison, Harriet E., scarlet fever treated with antifebrine, 481.
Gas, illuminating, nitroglycerine in poisoning by, 159.
Gastritis, chronic, resorcin in, 761.
Genital tuberculosis in women, 715.
Genito-urinary tract, tuberculosis of the, 432.
Genius and insanity, 597.
Georgia, medical legislation in, 655.
Georgia State Medical Association, forty-third annual meeting of the, 172.
German Physicians' Meeting, 225.
German Surgical Society, 77.
German universities, medical students in, 608.
Germany, the medical profession in, 102.
Getz, Charles, a new vaginal irrigator, 578.
Gibbons, John T., a neurosis? 589.
Gibney, Virgil P., the surgical treatment of acute arthritis of the hip in infants, 505, 517.
Gladstone and mastication, 47.
Glanders, new test for, 457.
Glaucoma, etiology of, 197.
Glioma, intra-ocular, following traumatic irido-choroiditis, 189; of the cord, 631.
Glycerine in hepatic colic, 435; intra-uterine injection of, 570, 576, 620.
Goitre, exophthalmic, 250; exophthalmic, treatment of, 354; surgical treatment of, 257; treatment of, 483.
Gonorrhœa in women, 429; in women, general aspects of, 407; in women, results of, 480; permanganate of potassium in, 352; peroxide of hydrogen in, 702.
Gonorrhœal conjunctivitis, 565.
Gonorrhœal joint affections, pathogenesis of, 208.
Gottheil, William S., clinical observations on europhen, 700.
Gout, chemistry and therapeutics of 174; in a child, 635; pathology and treatment of, 342.
Graphospasmus, 361.
Gravel and the uric acid diathesis, cause and treatment of, 129.
Gray, Henry V., a study of the relationship between the sphincter of O'Beirne and the valve of Bauhin in the functioning of the large intestine, 705; interrupted and conversion method of treating malaria, 531.
Green, Dr. James S., death of, 48.
Green, John Traill, absolute rest of the parts the best treatment for lesions of the vocal cords, 44.
Greene, Dr. Robert Warren, death of, 544; resolutions on the death of, 712.
Green, Dr. W. B., death of, 48.
Grier, W. F., toxic effects of antifebrin complicated with alcoholism, 511.
Griffin, E. Harrison, chancre of the mouth, 393.
Grocers' Company of London and scientific research, 717.
Groner, F. J., spina bifida, excision, recovery, 214.
Gross professorship of pathological anatomy, 683.
Guanajuato, insalubrity of, 355.
Guatemala, pharmaceutical law in, 600.
Guillotin, erection of a bust of, 634.
Gum-lancing, 351.
Gunshot wounds of the chest, prognosis of, 455.
Gynecologist, the general practitioner as a, 688.
Gynecology, fifty selected cases at the Woman's Hospital of New York, 499.

H

Hæmatemesis in cirrhosis, 435.
Hæmatocele resulting from tubal pregnancy rupturing into the broad ligament, 686.
Hæmoglobinuria, so-called malarial, 26.
Hæmolysis, 716, 744.
Hæmorrhoids, calomel for, 420, 565; ointment for, 493.
Hair, the, and surgical operations, 512.
Hall, A. L., creasote in the treatment of pulmonary tuberculosis, 151.
Hall, Rufus B., clinical report of gall-bladder operations, 497.
Halsted, T. H., adenoids in the naso-pharynx in children, 183.
Hamburg, cholera in, 439, 654.
Harelip operation, 690.
Harris, Charles H., abortion in an hour, 339.
Hartmann snare, a modified, 382.
Harvey, Thomas W., tubal pregnancy, 420.
Hats, the philosophy of, 513.
Haviland, Frank W., a needle in the ovary, 398.
Healey, Dr. Thomas M., death of, 220.
Healey, Joseph S., value of thorough vaginal tamponing in placenta prævia, 704.
Health, a national bureau of, 683.
Heart, a piece of steel in the, 348; action of atropine upon the, 709; chronic disease of the, 367; diffuse infiltrating sarcoma of the, 461; disease of the, from athletics, 745; eccentric hypertrophy of, 289; etiology of chronic disease of the, 541; extensive valvular disease of the, 378; heat to the epigastrium in failure of the, 412; increasing the intensity of the sounds of the, 75; musical murmurs of the, 288; new contributions to the physiology of the, 73; of a suicide, 713; thrombosis of the, 518; treatment of disease of the, 320; use of stimulants to the, in acute lobar pneumonia, 728, 743.
Height and health, 510.
Hemialbuminuria, 158.
Hemianæsthesia in father and daughter, 734.
Hemiparaplegia, syphilitic, 31, 50.
Hemorrhage by suggestion, 351; control of, after supra pubic prostatectomy, 331; post-partum, 285; post-partum, subcutaneous injections of a saline solution for the acute anæmia following, 395; post-partum, treatment of, 407; two cases of spontaneous intermittent, 362.
Hernia, congenital inguinal, in women, 755, 756; in infancy, 73; incomplete operation for, 713; inguinal, new instrument for treating, 629; radical treatment of, 686, 716; radical treatment of inguinal, 6, 756; retro-peritoneal tuberculosis simulating, 407; strangulated, 427; treatment of umbilical and ventral, 686; umbilical, in women, 410.
Hewlett, W. W., thrombosis of the pulmonary artery in the puerperal state, 591.
Hiccough, pilocarpine for, 635; red-pepper tea for, 348.
Hinde, Alfred, a case of toxic central amblyopia terminating in progressive atrophy, 70, 104.
Hindus, some advice from the ancient, 485.
Hip, double congenital dislocation of the, 629; old gunshot wound of the, 259.
Hip-disease, amputation in, 22; amputation through the thigh in, 662; case of cured, 79; classification of, 436; etiology of the various deformities of, 437; reflexes in, 510; surgical treatment of acute, in infants, 505, 517.
Hog-cholera, vaccination for, 478.
Holder, A. B., papers on diseases among Indians, 177, 329, 357.
Hooper, Dr. Franklin H., death of, 654.
Hospitals, field, location of, 77; in London, 91.
Hubbell, M. D., eyes of different colors, 279.
Huddleston, John H., three cases of malaria in children treated successfully by methylene blue, 191.
Hunter, D. W., a combination test-cord, 579.
Huntington's chorea, a case of, 222; congenital, 137.
Husband, Mr. William Dalla, death of, 252.
Huxley on the title of "doctor," 328.
Hyaloid artery, posterior capsular opacities at the place of attachment of the, 199.

Hydatid cyst of the liver, 603.
Hydræmia, septic, following miscarriage, 286.
Hydrastinin in epilepsy, 310.
Hydrastis canadensis in obstetrics, 192.
Hydrogen peroxide in dermatology, 93; in diphtheria, 425; in gonorrhœa, 702.
Hydrocephalus, chronic, paroxysmal tetanic spasm in, 249.
Hygiene, bureau of, at the World's Fair, 745.
Hymen, anatomy of the, 288.
Hyperidrosis of the hands and feet, 411.
Hyperphoria, prominent symptoms of, 199.
Hypnotism as a moral force, 356.
Hypodermoklysis, 567.
Hypogastric artery, ligature of the, 23.
Hysterectomy for carcinoma, 408; for carcinoma complicated with myomata, double hydrosalpinx, and cystic ovaries, 603; suprapubic, 583; vaginal, in malignant diseases of the uterus, 29, 30, 49.
Hysteria, Hippocrates on, 75; treatment of, 16.
Hysterical patient, fourth laparotomy on an, 726, 743.

I

Ice, in Paris, purifying the source of, 496; in relation to cholera, 313; value of application of, over the spine, 127.
Ice-water, a plea for, 488.
Ichthyol in dermatology, 93.
Ileum, excision of a cancerous growth of the, 745.
Ilium, sciatic neuralgia due to osteo-sarcoma of the, 80.
Incomes of medical men, 28; in Berlin, 543.
Incoördination, combined cerebellar and spinal, 134.
Indians, diseases among, 177, 329, 357.
Inebriates, female, and special legislation, 422.
Inebriety, alleged gold-cure of, in London, 102, 218, 316; among women, 544; strychnine in, 636.
Infancy, hernia in, 73.
Infant, an, born with teeth, 589; scorbutus in an, 419, 575; spontaneous reduction of intussusception in an, 678.
Infants, rules for the care of, 83; surgical treatment of acute hip-disease in, 505, 517.
Infection, to prevent the spread of, in Detroit, 634.
Influenza, myelitis following, 418; some pathological conditions of the upper air-passages coincident with attacks of, 105.
Infusion, arterial saline, 559.
Ingals, Ephraim, the sanitary condition of Chicago, 719.
Inhalers, anæsthetic, a new feature of, 608.
Insane, a modern asylum superintendent's view of the care of the, 736; colony system for the, in France, 345; woman physicians in asylums for the, 350.
Insanity and genius, 597; and sun-spots, 281; in the United States, decrease of, 628; increase of, 542; nature of, 491; of egotism, 592; phthisis in its relation to, 139; sensory and sensory-motor disturbances associated with, 139; toxic origin of, 138; types of, similar to folie à deux, 137.
Insomnia and mental depression, 597; treatment of, 595.
Insufficiencies, ocular, tenotomy of the recti muscles for, 199.
Intestinal anastomosis, 257; by a new device, 687; without sutures, 665.
Intestinal invagination, dangers of, subsequent to operation, 188.
Intestinal obstructions, diagnosis and treatment of, 85; gangrene of the lower limbs following, 550.
Intestinal surgery, experimental contribution to, 335.
Intestinal sutures, 550.
Intestine, large, relationship between the sphincter of O'Beirne and the valve of Baubin in the functioning of the, 705; perforation of, by a spoon, 471; small, resection of the, 746.
Intubation of the larynx, for chronic stenosis, 106; versus tracheotomy, 545.
Intussusception in an infant, spontaneous reduction of, 678.
Iodine trichloride in surgery, 66.
Iodoform, an improved box for, 204; deodorized, 95.
Irido-choroiditis, traumatic, ending in intraocular glioma, 189.
Iris, tuberculosis of the, 539.
Iritis, etiology of, 512; plastic, correction of manifest refractive error in, 198.
Iron, therapeutic uses of, 264.
Irrigation-tubes, accessory sinus, 607.

J

Jackson, Dr. A. Reeves, death of, 628.
Jackson, Chevalier, a practical transilluminator, 521.
Jamaica, the healing waters of, 626.
Janvrin, J. E., the limitations for vaginal hysterectomy in malignant diseases of the uterus, 29, 49.
Japan, rheumatism in, 355.
Jaw, dislocation of the, 579.
Jejunostomy, a new method of, 351.
Johnson, Charles C., death of, 103.
Johnson, Ira T., transposition of the viscera, 397.
Johnston, Dr. Francis Upton, death of, 737.
Joint amputations, 24.
Joint-lesions, three cases of unusual, 436.
Joints, pathogenesis of gonorrhœal affections of, 208; permanent warm bath in inflammation of, 507.
Jones, Dr. Montgomery, death of, 738.
Jones, E. L., two cases of hemialbuminuria, 158.
Jones, Isaac J., so-called malarial hæmoglobinuria, 26.
Jones, Jonas, obituary of, 684.
Journalism, honest, the dangers of, 655.
Jugular veins, compression of the internal, with intranasal medication in the localization of the action of remedies on the brain, 749.

K

Kaufman, J., an infant born with teeth, 589.
"Keeley cure" in London, 102, 218, 316.
Kelly, Howard A., confinement on the obstetric pad, 663.
Kennedy, James, amputation of the thigh for tuberculosis of the tibia, 214.
Keratitis, treatment of vesicular, 159.
Keratosis, original, 383.
Keyes, E. L., an efficient method of controlling hemorrhage after supra-pubic prostatectomy, 331.
Kidney, a large hydronephrotic, 430; absence of one, 518; digitalis in disease of the, 539, 633; exploration of, for renal colic, 222; extirpation of the, for tumor, 746; horseshoe, 518, 589; movable, 576; movable, and diseases of the generative organs in the female, 469; movable, seldom found at autopsy, 602; movable, vomiting in, 624; removal of a tumor of, from a child two years old, 431; rupture of the, during parturition, 378; sarcoma of the, 430; syphilis of the, surgically considered, 159
Kimball, Dr. J. Albert, death of, 219.
Kime, Sara A., female physicians in insane asylums, 350.
Kinnaman, A. S., treatment of fracture of the clavicle, 214.
Kinnear, B. O., ice scientifically applied over the spine is agreeable as well as beneficial to the patient, 127.
Knee joint, an unique derangement of the, 57, 80; injuries of the, 429; lateral dislocation of the, due to tubercular disease or paralysis, 436; six cases of excision of the, 438.
Koehler, F. W., an improved stethoscope for use in auscultatory percussion, 576.
Krog, Albert, a case of vaginismus, 42; fracture of the penis, 397.
Krouse, L. J., procto-plastic operation for the cure of cicatricial stenosis of the anus, 506.

L

Labium majus, epithelioma of the right, 289.
Labor, adhesion of the nymphæ after, 576; cœliotomy after, 406; induction of, by intra-uterine injections of glycerine, 570, 576, 620; value of the forceps in complicated high arrest of the breech, 410.
Lactation and menstruation, 632.
Lamblin abdominal needle, 263.
Laminectomy, 258; for Pott's paraplegia, 593.
Lane, Mr. Samuel Armstrong, death of, 252, 291.
Langenbeck House in Berlin, 48.
Laparotomy after labor, 406; fourth, on an hysterical patient, 726, 743.
Laryngectomy, partial, for extensive carcinoma, 631
Laryngoscopy, Frau Gelby of Vienna as a living model for the practice of, 571.
Larynx, death from impaction of meat in the, 602; epithelioma of the, 289; extirpation of the, 79, 157; extraction of a safety pin from the, 214; rare forms of growth in the, 106.
Lateral curvature of the spine, 437.
Lautenbach, Louis J., the ancient history of a new ear instrument, 262.
Lead-poisoning from a bullet, 636.
Leaming, Dr. James R., obituary of, 684; resolutions on the death of, 712.
Lee, Elmer, practical experiments in the treatment of cholera in St. Petersburg and Hamburg in 1892, 693.
Legislation, need of national, for the protection of human life, 27.
Leprosy, etiology of, 293, 632; in the Caucasus, 112; operation for, 78; pure cultures of the bacillus of, 53.
Lesbian love and murder, 104.
Letters from Berlin, 225, 349, 439, 606, 746; from Canada, 747; from London, 54, 81, 173, 290, 379, 462, 491, 519, 549, 604, 661, 690, 716, 744; from the Riviera, 108, 200, 226, 323, 463.
Leukæmia, rapidly fatal, after traumatism, 595.
Levy, Sigfred, contribution to the treatment of club-foot, 528.
Lewinthal, David C., a dilating trocar, 522.
Lichen planus treated by hydrotherapy, 311.
Licorish, R. F., delirium tremens, has it a dual origin? No! 55.
Liebig, A., diphtheria and its relationship, 585.
Ligaments, round, shortening the, 588.
Linsley, Joseph H., micro organisms of the mouth, 59.
Literature, the physician and, 176.
Lithopedion, a, 53, 405.
Littlejohn, Eugene M., San Antonio and Southwest Texas as a winter resort, 588; the Rocky Mountain region for consumptives, 152.
Liver abscess of the, 353, 433; acute yellow atrophy of the, 430; acute yellow atrophy of, and syphilis, 506; difficulties of diagnosis in lesions of the, 222; hydatid cyst of the, 603; phlebotomy of the, 163; resection of, for hepatic tumors, 679; rupture of an abscess of the, 717; sclerosis of, and the hepatic cell, 539; surgery of the, 254, 256.
Livingston, Dr. Watts C., obituary of, 739.
Locomotor ataxia, 631; Bonuzzi's treatment of, 368.
Locum tenens, the, 290.
Lodging-houses, wire mattresses and provision for isolation in, 738.
London, hospitals in, 91; letters from, 54, 81, 173, 290, 379, 462, 491, 519, 549, 604, 661, 690, 716, 744.
Longenecker, C. B., the essentials of a good stethoscope, 575.
Louise Lateau, a modern, 746.

Ludlow, Ogden C., use of electricity in midwifery, 729.

Medical Society of Virginia, 426.
Medicine and morals, 355.
Meding, C. B, physician heal thyself, 210.
Medulla oblongata, apoplexy of the, 547.
Melancholia, castration for, 736.
Melano-sarcoma with melanuria, 659.
Meningeal artery, middle, rupture of the, 260.
Meningitis, basilar, occurring in a case of chronic purulent otitis media, 166; cerebro-spinal, 322; cerebro-spinal, the pneumococcus in, 128.
Meningocele, lumbar, successful removal of a, from an adult, 64, 80.
Menopause, first sign of the, 191.
Menstrual periods, periodical pain between the, 405.
Menstruation and lactation, 652.
Mentone, 463.
Mercurial tremor, question of the existence of, 483.
Mercury, in cholera, 633; presence and localization of, in the system, 623.
Metabolism, possible electric polarity of, 265.
Mettler, L. Harrison, the sensory-motor functions of the brain, 238.
Mexican Medical Congress, the first annual, 711.
Mexico, medical practice in, 543.
Meyer, E. J., a retractor for amputations, 140.
v. Meyer, Dr. Georg Hermann, death of, 316, 350.
Micrococcus pyogenes aureus, test reaction for the culture of, 70.
Microbe of soft chancre, 281.
Microbes, as chemists, 412; improved method of photo-micrography of, 698.
Micturition, frequent, phenacetin for, 420; restoration of the lost function of, 258.
Midwifery, reprehensible, unnecessary, and necessary antiseptic, 576; use of electricity in, 729.
Milk, sterilization of, at a low temperature, 8.
Millard, Henry B., a summary of what can be accomplished in the treatment of chronic Bright's disease, 385.
Millennium, is it at hand? 423.
Miller, John S., an improved shot compressor, 692.
Milliken, Samuel E., the radical cure of inguinal hernia—Bassini's method illustrated, with remarks on recurreat and ventral hernia, 6.
Mineral springs of Jamaica, 626.
Miscarriage, septic hydræmia following, 286.
Misericordia, the, of Florence, 356.
Missionary, the medical, 263.
Missionaries, superiority of medical over clerical, 112.
Mitchell, S. Weir, precision in the treatment of chronic diseases, 721.
Mittendorf, W. F., two cases of metastatic choroiditis, 245.
Models, anatomical and pathological, a new material for, 50.
Moles, tubal, 661.
Mollinger, Father, the remedies of, 347.
Money, paper, bacteria on, 253.
Moral side of medical practice, 652.
Morton, William James, a possible electric polarity of metabolism, and its relations to electro-therapeutics and electro physiology, 265; the introduction of anæsthesia, 719.
Morvan's disease, a form of leprosy, 496.
Mosquitoes in London, 355.
Mountain climbers, fatal accidents to, 662.
Mouse typhus, extermination of field-mice by, 349.
Mouth, chancre of the, 393; micro-organisms of the, 59.
Mulattoes, offspring of, 551.
Mumps, Hippocrates on the, 75; troubles of salivary secretion in, 479.
Munger, Carl E., a modified Gottstein's curette, 291.
Murdoch, Frank H., an unusual case of pneumothorax, 43.
Murphy, J. B, intestinal anastomosis and approximation without sutures, 665.
Murray, Alan B., treatment of carbuncle by injection of carbolic acid, 455.
Muscular sense, the, 135.
Mutilations, hereditary transmission of, 103.
Myelitis, acute, of the dorsal cord, with rapidly fatal motor and sensory paralysis, 137; compression, a case of, 52; following catarrhus epidemicus, 418.
Myles, Robert C., accessory sinus irrigation tubes, 607.
Myocarditis, interstitial, 432.
Myopia, full correction of, 197.
Myxœdema, fresh thyroid gland as a food in, 571; subcutaneous injections of thyroid extract for, 580.

N

Nævus of the peritoneum, 550.
Nagle, John T., some thoughts on contract medical services, 521.
Naphthol in dermatology, 92.
Napoleon, the pulse of, 328.
Nasal asthma alternating with circumscribed œdema of the skin, 539.
Nasal douche, substitute for the, 565.
Nasal spray and palate retractor, a combined, 579.
Navy, work in Venezuela by medical officers of the, 653, 711.
Negro, chorea in a, 215; the eye of the, 199; vitiligo in a, 575; yellow fever and the, 261.
Nelson, J. O., the sterilization of catgut, 748.
Nerve currents, hearing the, 514.
Nervous disease during Græco-Roman antiquity, 510; traumatic, 138; treatment of chronic, in patients of the rheumatic diathesis, 309; treatment of syphilitic, 138.
Nervous women, types and treatment of, 523.
Neuralgia, facial, formula for, 440.
Neurasthenia, new cure for, 343; objective signs of, 479.
Neurectomy of the sciatic for neuroma, 25; of the trigeminal at the foramen ovale by Sulzer's method, 742.
Neuritis, peripheral, 318; two cases of, 534.
Neurology, outlook of, 126.
Neuroma, ganglionic, of the supra-renal capsules, 51.
Neuropathies, toxic, 541.
Neuroses in chronic rheumatoid arthritis, 322; treatment of, with microbic ferments, 627.
Neurosis, a, 589.
Neurotic asthma, early symptoms of, 539.
New Jersey, medical history of, for 1891, 170.
New Mexico Medical Society, 402.
New York Academy of Medicine, 489, 545, 601, 741; anniversary meeting, 627; report of the conference committee of the, 516. Section on Public Health, 370, 375; Section on Obstetrics and Gynecology, 576; Section on Surgery, 79, 629.
New York City, number of physicians in, 48.
New York County Medical Association, 548, 713.
New York Hospital Alumni Association, 711.
New York Pathological Society, 50, 259, 288, 377, 430, 461, 518, 547, 602, 658.
New York Post-Graduate School and Hospital, laying the corner-stone of the, 656.
New York State Medical Association, Fifth District Branch, 49.
Newton, Richard Cole, successful extraction of a bottle from the bladder, 259.
Nice, typhoid fever at, 636.
Night-sweats of phthisis, picrotoxine in, 735.
Nipples, sore, ichthyol for, 623.
Nitroglycerine, dose of, 224; in poisoning by illuminating gas, 159.
Nomenclature of disease, 549.
Nose, after-results of cauterization of, 107; correction of deformity arising from abscess of the septum, 107; cosmetic surgery of the, 24; medication of the mucous membrane of the, combined with compression of the internal jugular veins, as a means of localizing the action of remedies upon the brain, 749; more common forms of stenosis of the, 715; red, application for a, 354; relation of aural and nasal affections, 148; removal of a shoe-button from the, 603.
Nurses and religion, 28; association of visiting, in Chicago, 75; post-graduate course for, 316.
Nursing knows no creeds, 355.
Nymphæ, adhesion of the, after labor, 576.
Nystagmus among colliers, 757.

O

Oakley, Mrs. John M., to repress expectoration in public places, 140.
Oatmeal pyrosis, 264.
Obermueller, Dr , death of, 284.
Obstetric pad, confinement on the, 663.
Obstetrics, notes on conservative, 212; scientific, at Winkel's clinic in Munich, 655.
Œdema of the skin, circumscribed, alternating with nasal asthma, 539.
Œsophagus, removal of a peach-stone from the, 716; safety-pin impacted in the, 431.
Oklahoma, medical practice in, 493.
Old age, operations in, 539; ovariotomy in, 689; phthisis in, 681.
Omentum, tumors of, mistaken for pelvic tumors, 601.
Onions in cholera, 684.
Ontario, medical council of, 747.
Onuf-Onufrowicz, B., post partum hemorrhage followed by sepsis—treatment of the acute anæmia by subcutaneous injections of a saline solution—recovery, 395.
Oöphoro-salpingitis, new treatment of, 460.
Opacities, posterior capsular, at the place of attachment of the hyaloid artery, 199.
Ophthalmia, treatment of granular, by pyoktanin, 480.
Ophthalmometer of Javal-Schiotz, some practical uses of the, 577.
Opium, a moderate use of, opinion of the life insurance companies upon, 572; a struggle with, 634; defence of the use of, by the women in India, 496.
Opium-habit, medical defence of the, 251.
Opportunities, Sir John Lubbock on the use of, 491.
Orbit, cellulitis of the, 200.
Orchid tea, 347.
Orificial surgery, 104, 355.
Orme, H. S., leprosy and syphilis, 632.
Osteitis deformans, 436.
Osteoclasia for knock-knee and bow-legs, 438; specimen showing the result of, 547.
Otitis media, and optic neuritis, 166; antiseptic solutions in purulent, 167.
Ovarian tumor, pregnancy with, 216.
Ovariotomy in cases of general neurosis, 440; in old women, 689; in the presence of peritonitis, 308; prevention of secondary hemorrhage after, 409.
Ovary, a needle in the, 398; and tube, cystic lesions of the, 377; circumscribed ascites simulating tumor of the, 715; cyst of the, and fimbriæ of the tube, 288; morphology of tumors of the, 688.
Overholt, S., a case of malignant tumor of the femur in a boy aged thirteen, occurring in the practice of E. J. Smith, M.D., 44.
Owen, Sir Richard, obituary of, 739.
Oxychinaseptol, 132.
Ozæna, treatment of 419.

P

Paget's disease, fuchsin in, 164.
Pain, periodical inter-menstrual, 405.
Palate retractor and post-nasal spray, a combined, 579.
Panama, the health of, 348.
Pan-American Medical Congress, 403; influence of, on sanitation and quarantine, 548; prospects of the, 624; State aid for the, 654.
Pancreas, injury of the, 255.
Paris doctorate, questions at the examination for, 164.
Paris, water-supply of the suburbs of, 384.
Paralysis, pneumonic, 542; pressure, operation for, 79; rapidly fatal motor and sensory, with acute myelitis of the dorsal cord, 137.
Paraplegia of Pott's disease, laminectomy for, 593.
Park, William Hallock, diphtheria and allied pseudo-membranous inflammations, 113, 141.
Parker, Francis L., extraction of a safety-pin from the larynx with Mackenzie's forceps, 214.
Parker, William Thornton, does she do it? 633.
Parturition, rupture of the kidney during, 378.
Pasteur Institute in New York, 552.
Peabody, George L., feeding in fevers, 620, 631.
Pelvic affections, electrical methods as a substitute for surgery in certain, 428.
Pelvic cellular tissue in woman, 601.
Pelvic operations, drainage after, as influenced by preliminary curettage of the uterus and Trendelenburg's position, 529.
Pelvic peritonitis, abdominal section in, 519, 691.
Pelvic surgery, advances in, 685; complications during and after operations in, 405.
Pelvis, treatment of hard tumors of the, 430.
Pemphigus neuroticus, 176.
Penis, fracture of the, 397.
Pental, death under, 351; narcosis by, 79.
Pericarditis, ice in, 320.
Perineum, laceration of the, 186.
Peritoneum, nævus of the, 550.
Peritonitis, ovariotomy in the presence of, 308; pelvic, abdominal section in, 519, 691; surgical treatment of puerperal, 172; traumatic, 661; tubercular, spontaneous cure of, 690; tubercular, treatment of, 689.
Perraza, Dr. José Miguel, death of, 402.
Pertussis, etiology of, 746.
Peterson, Frederick, some practical points in the diagnosis of spinal cord lesions, 553; wintering in Egypt, 205.
Pharyngo mycosis, 105.
Phenacetin in vesical irritation, 593; peculiar vaso-motor disturbance after the administration of, 341.
Phlebotomy, visceral, 23, 163.
Phosphorescence, bacteria of, 565.
Phthisis, cold-air treatment of, in the case of a Russian Grand Duke, 17; eucalyptus honey for, 28; importance of symptom-treating in, 715; in its relation to insanity, 139; in later adult life, 681; influence of diathesis upon the progress of, 651; non bacillary, 351; picrotoxine in the night-sweats of, 735; the urine in, 679; Tyndall on, 411. See also *Tuberculosis.*
Physical education, a congress of, 28; compulsory, 424.
Physician, a faithful district, 738; heal thyself, 210.
Physicians, family, a syndicate of, 738; and the right of way, 572; number of, in Ontario, 748; the comfort of, 737.
Physicians' accounts, 718.
Physics and physic, 491.
Physiologists, Second International Congress of, 372.
Picrotoxine in the night-sweats of phthisis, 735.
Pierson, William, tubal pregnancy, 420.
Pilocarpine for hiccough, 635; in labyrinthine deafness, 191.
Pityriasis versicolor, 539; internal treatment of, 569.
Placenta prævia, thorough vaginal tamponing in, 704.
Placzek, S., hemianæsthesia in father and daughter, 734.
Plants, diseases of, 318.
Plaster-of-Paris in orthopedics, 430.
Pleural effusions, surgical treatment of, 254.
Pleurisy and rheumatism, analogy between, 22.
Pleuro-pneumonia, and empyema, 52; removal of quarantine against, 402.
Pneumathæmia, 707.
Pneumococcus in cerebro-spinal meningitis, 128.
Pneumonia, digitalis in, 704; genesis of, 21; lobar, possibly of microbic origin, 462; paralysis following, 542; pathology of sudden death in, 171; rational treatment of, 147; serum treatment of, 540; treatment of, 172; treatment of, by the artificial production of abscesses, 368; use of heart-stimulants in acute lobar, 728, 743.
Pneumothorax, unusual case of, 43.
Podrowsotski, Dr. Valerian, death of, 252.
Poisoning by sulphonal, 523
Post-Graduate Hospital of New York, laying of the corner-stone of the, 656.
Post graduate instruction, for nurses, 316; the success of, 682.
Post-mortem examinations of animals and birds, 368.
Post-partum hemorrhage, subcutaneous injections of a saline solution for the acute anæmia following, 395; treatment of, 407.
Pott's disease associated with fibrinous, peritoneal, and pleuritic adhesions, 602; rotary lateral deformity of the spine in, 333; surgery of, 192; ultimate deformities of, 437.
Pott's paraplegia, laminectomy for, 593.
Powers, Charles A., the treatment of spina bifida by excision, with report of the successful removal of a lumbar meningocele from an adult, 64, 80.
Practical side of medical practice, 653, 717.
Practitioners' Society of New York, 222, 517, 631, 742.
Pravaz, Dr., death of, 194.
Pregnancy, extirpation of a cancerous uterus in the sixth month of, 680; extra-uterine, 523; tubal, 420; tubal, ruptured, 433; twin tubal, 286; vomiting of, cocaine for, 496; vomiting of, menthol for, 494; with ovarian tumor, 216.
Prescriptions, ownership of, 424.
Prince, A. E., an extreme case of suspended animation from chloroform resuscitated by direct insufflation in the inverted position, 340.
Prince, a medical, 424.
Prize, for an essay on tuberculosis, 152; for the invention of a microphonic audiphone, 514, 636; offered by the Medical Temperance Association, 485; the Alvarenga for 1893, 598; the Riberi, 373; the Warren triennial, 515.
Probes and probing, 630.
Proprietary medicines, enforcing the fulfilment of promises made by advertisers of, 384; resolutions against, 75.
Prostate gland, new method of removing the, 147; operation for enlarged, 258.
Prostatectomy, control of hemorrhage after, 331.
Prostitution, regulation of, 253, 283, 567, 708.
Pruritus vulvæ, cured by the constant current, 311; wash for, 579.
Pryor, William R., drainage after pelvic operations as influenced by preliminary curettage of the uterus and Trendelenburg's position, 529.
Psoriasis, 541; a neurosis of the skin, 311; gallacetophenone for, 353; treatment of, 36.
Psorospermosis, 622.
Ptyalism and dysentery, 538.
Puerperal fever, 427.
Pulmonary artery, thrombosis of the, in the puerperal state, 591.
Pyæmia following acute suppurative otitis, 166.
Pyle, J. S., a new method of removing the prostate gland, 147; supra-pubic hysterectomy as performed with a set of new instruments devised for the purpose, 583.
Pylorectomy and vivisection, 655.
Pylorus, stenosis of the, 78.
Pyoktanin in dermatology, 94; in diphtheria, 706; in the treatment of granular ophthalmia, 480.
Pyonephrosis, anomaly of the liver mistaken for, 224.
Pyrosis from oatmeal, 264.
Pyrozone in dermatology, 93.

Q

Quacks, enforcing the fulfilment of advertised promises of, 384; itinerant, legislating against, 346; running down the, 572.
Quarantine, administration of the present laws of, 373; an English view of, 372; an ill-timed criticism of the New York, 281; and cholera, 344; at New Orleans, 369; Canadian, 748; establishment of a national, 708, 738; establishment of a twenty-day, 314; increased facilities for, 343; period of detention at, 373; report of the New York Chamber of Commerce on, 712; success of, in New York, 484; suggestions relating to improvement of, 581.
Quimby, Charles E., the treatment of ulcers by strapping, 755.
Quinine, hypodermic use of, 353; in cholera, 399, 676.

Symphyseotomy, 506; first successful case of, in this country, 543; remarkable results of antiseptic, 406.
Symptoms in perspective, 550.
Syphilis, and acute yellow atrophy of the liver, 506; and uterme fibroids, 542; as a defence of breach of promise, 514; duration of treatment of, 370; lamb's blood-serum in, 493; occulta, 352; prevention of, 322.
Syphilitic nervous affections, treatment of, 137.

T

Tachycardia, 456, 539; paroxysmal, treatment of, 493.
Talipes, equino-varus, 25; equino-varus, open incision for, in an adult, 80; equino-varus, radical treatment of, 717; etiology and treatment of, 437; treatment of, 528; see also *Club-foot*.
Tanfani, Dr. Enrico, death of, 219.
Tapeworm, increasing prevalence of, 594; salicylic acid for, 348.
Tariff, relation of the medical profession to the, 654.
Taylor, Dr. Clarence O., death of, 252.
Teal's rectangular flap operation, modification of, in amputation of the extremities, 248.
Teeth, an infant born with, 589.
Tendoplastic operation, 495.
Tenon's capsule, inflammation of, in mercurial poisoning, 200.
Terry, Dr. C. C., death of, 103.
Test-card, a combination, 579.
Testis, ectopia of the, 157.
Tetanus, 426; immunity from, 249; observations on, 352; treated by cold baths, 680; treated by the Tizzoni-Cattani antitoxin, 132.
Tetronal and trional, 356.
Texas, trouble in, 401.
Thallin in typhoid fever, 594.
Thiersch's skin grafting for webbed fingers, 631.
Thilanine, 82; in dermatology, 95.
Thiophendiodid, 74.
Thiosinamine in lupus, 744.
Thorax, surgery of the, 254.
Throat, operations upon the, influence of certain diathetic conditions upon the prognosis in, 105.
Thrombosis of the pulmonary artery in the puerperal state, 591.
Thyroid extract, subcutaneous injection of, for myxœdema, 580.
Thyroid gland, the fresh, as food, 571.
Tibia, tuberculosis of the, amputation of the thigh for, 214.
Tingley, W. K., peculiar vaso-motor disturbance after the administration of phenacetine, 341.
Tinnitus aurium, cocaine in, 479.
Tobacco and cholera, 711; and the tobacco habit, 482; consumption of, in Great Britain and France, 356.
Tobacco smoke, antiseptic property of, 10, 262.
Tongue, fibrous epithelioma at the root of the, 106.
Tonic after a debauch, 354
Tonsillotomy, new method of checking bleeding after, 699.
Tooth culture, 551.
Toothache, reflex, 496.
Toronto University, recent election to the Senate of, 747.
Torticollis, spasmodic, 629.
Tracheotomy, creosote in, 351; versus intubation, 545.
Transfusion, case of instruments for, 576; monument to the reviver of, 599.
Transilluminator, a practical, 521.
Trembling, hysterical, and anorexia nervosa, 136.
Trephine, when to, 565.
Trephining, exploratory, 137; for cranial injury, 742.
Trichiniasis, microscopic specimens from, 743.
Tricophytosis capitis, treatment of, 352.
Trigeminus, resection of the, 78.
Trional and tetronal, 356.
Trocar, a dilating, 522.
Trolley wire, a doctor injured by, 572.
Tropa cocaine and tropine, 628.
Tryon, Dr. Rufus J., honors to, 711.
Tubal moles and tubal abortion, 661.
Tubercle bacilli, growth of voluminous cultures of, 378.
Tubercular peritonitis, spontaneous cure of, 690; treatment of, 689.
Tuberculosis, bedbugs as carriers of, 347; congress for the study of, 281; creasote in the treatment of, 151; dissemination of, by earthworms, 279; general, 51; genital, in women, 715; hypodermic use of gold and manganese in, 303; in Egypt, 320; in later adult life, 681; in the White House, 512; miliary, and gummata in the same lung, 659; miliary, of the lungs and kidneys, 660; of the bones and joints, 78; of the eye, 539; of the genito-urinary tract, 432; of the tibia, amputation of the thigh for, 214; Pennsylvania Society for the Prevention of, 543; pharyngeal, lactic acid in, 690; prevention of, 322; primary, of the urethra, simulating stricture, 248; prize for essay on, 152; retro-peritoneal, simulating hernia, 407; Rocky Mountain region for sufferers from, 152; smoke as a curative agent in, 444; see also *Phthisis*.
Turn-table for collecting sediments from fluids, 53.
Turpentine stupe, death from the ignition of a, 328.
Tyndall on phthisis, 411.
Type, origin of, in disease, 441.
Typhoid bacillus, vitality of the, 539.
Typhoid fever, an epidemic of, 348; antisepsis in, 292; antiseptic oxygenation in, 514; cool baths in, 352; disorders of the ears in, 273; respiratory prodromes of, 480; results of expectant treatment in, 609; some points in the etiology of, 54; sterility following, 5; the nervous sequelæ of, 398; thallin in, 594.
Twins, insuring against, 552.

U

Ulcer of the stomach, resorcin in, 595.
Ulcers, dysenteric, 259; of the leg, 258; of the leg, treatment of, by strapping, 754.
Umbilical hernia in woman, 410.
Umbilical cord, œdema and inflammation of the, 377.
Ureter, occlusion of the right, with cystic degeneration of the left kidney, 51.
Ureters, a case of three, 755; implantation of the, into the rectum, 23; surgery of the, 688.
Urethra, nematode parasitic worm in the, 432; primary tuberculosis of the, simulating stricture, 248; treatment of the, 175.
Uric acid gravel, causes and treatment of, 173; chemistry of, 81; treatment of, 352.
Urine, blood in the, how to discover its source and what to do for it, 525; in phthisis, 679; of high specific gravity, 538.
Urticaria, treatment of, 132, 353.
Uterus, association of cancer and fibroids of the, 678; atresia of the cervical canal resulting from syphilitic ulcers, 190; cimicifuga in disorders of the, 291; diarrhœa from retroflexion of the, 735; disease of, simulated by abnormal conditions of the abdominal organs and tissues, 601; Dudley's operation on the cervix, 589; extirpation of a cancerous, in the sixth month of pregnancy, 680; extirpation of the, 79; fibroid tumor of, complicating pregnancy, 260; fibroids of the, and syphilis, 542; hysterectomy for fibroids of the, 409; injections of glycerine to stimulate contractions of the, 620; interstitial and submucous fibro-myoma of the, 433; malignant adenoma of the, 432; new instrument for dilatation of the cervix, 713; operations for cancer of the, 408; polypoid hypertrophy of the mucous membrane of the, 603; polypoid spindle-celled sarcoma of the, 288; radical cure of retroflexion of the, 286; rupture of, in the fourth month of pregnancy, 686; sarcoma of the, 576; treatment of fibroids of the, 286; vaginal hysterectomy in malignant diseases of the, 29, 30, 49; various forms of cervical inflammation, 689.

V

Vaccination and small-pox, 354.
Vaccine virus, propagation and preservation of, 391; transportation of, by carrier-pigeons, 608.
Vagina, neoplasms in the, 479.
Vaginal irrigator, a new, 578.
Vaginismus, a case of, 42; treatment of, 494.
Valentine, R. K., an improved stethoscope, 82.
Vanderpoel, Edward, cholera in New York in 1832, 412.
Van Voast, Dr. George W., death of, 104.
Varicocele, cremasteric reflexes in, 22.
Varicose veins and sciatica, 351.
Variola, varioloid, and varicella, 479.
Veins, air in the, 25.
Venereal diseases, periodicity of, 565.
Venesection, 33, 162, 320.
Venezuela, surgical work of foreign naval officers in, 653, 711.
Ventilation by means of heated walls, 356.
Vertebral artery, ligation of the, 137.
Vertex, occipito-posterior positions of the, the best management of, 410.
Vertigo, 426; aural, and drowning, 710.
Vienna, University of, 515.
Villemin, Dr., death of, 635.
Virchow, speech of, on assuming the rectorate of the University of Berlin, 607.
Viscera, transposition of the, 397.
Visceral disease, association of sensory disorders with, 322.
Visual area of the cortex of man, extent of, 136.
Visual fields, intra cranial lesions with defects in the, 199.
Vivisection, controversy over, 457, 482, 485, 515, 519, 683, 745.
Vitreous chamber, removal of a fragment of steel from the, by the electro-magnet, 197.
Vitiligo in a negro, 575.
Vocal cords, absolute rest is the best treatment for lesions of the, 44; bilateral paralysis of the abductors of the, 706.

Voice, influence of diet and digestion on the, 713; the falsetto, 536.
Volvulus, traumatic, 605.
Vomiting, feigned, of blood, 744; in floating kidney, 624; of pregnancy, cocaine for, 496; of pregnancy, menthol for, 494.
Vondergoltz, Eric, the internal use and dosage of lysol, 367.
Voris, S. M., effects and causes of laceration of the perineum, 186.
Vulva, pruritus of the, cured by the constant current, 311.
Vulvo-vaginitis in children, 707.

W

Waechter, C., an improved catheter, and some remarks about treating the urethra, 175.
Wagner, Clinton, a case of bilateral paralysis of the abductors of the vocal cords, 706.
Wall, John P., rigidity after death from strychnine, 718.
War, mortality of, 28.
Warren, Lillie Eginton, teaching deaf children to hear, 473.
Warts, porpoise blood for, 18.
Washburn, W., digitalis in kidney disease, 633.
Water, filtered or boiled, 595; germ-free, 635; purification of, 356; simple tests for impurities in, 496; small daily allowance of, 574.
Watkins, Robert L., an electric machine for the production of all kinds of electricity for medical purposes from a single storage battery, 262.
v. Wedekind, L. L., nine cases of gonorrhœa treated with undiluted peroxide of hydrogen, 702; myelitis following catarrhus epidemicus, 418.
Weigert's recent staining for the nervous system, 260.
